Chemistry and Mechanism of Action: Gemcitabine (2′,2′-difluorocytidine monohydrochloride) is a nucleoside analog that differs from 2′-deoxycytidine by virtue of the presence of fluorine atoms in the 2′α and 2′β positions of the cytidine ring. It is transported across the cell membrane by facilitated nucleoside diffusion, phosphorylated by deoxycytidine kinase, and ultimately converted to its lethal metabolites, dFdCDP and dFdCTP. The diphosphate form (dFdCDP) inhibits ribonucleotide reductase, leading to disruption of dNTP pools and resultant interference with DNA synthesis and repair. The triphosphate form (dFdCTP) competes with dCTP for incorporation into DNA. Reductions in dCTP pools (secondary to ribonucleotide reductase inhibition) result in self-potentiation of gemcitabine action. Incorporation of gemcitabine into DNA in S phase inhibits elongation of the replicating strand, leading to DNA chain termination. The lethal actions of gemcitabine in leukemia cells have been related to the induction of apoptosis and are not restricted to cells actively engaged in DNA synthesis. Gemcitabine has been shown to be considerably more potent in inducing apoptosis in cultured human leukemia cells than ara-C.

Absorption, Fate, and Excretion: In studies involving intravenously administered labeled gemcitabine, up to 98% of the drug was recovered in the urine after 1 week. The excreted dose was composed of a minor fraction (gemcitabine; <10%) and inactive metabolites (e.g., 2′-deoxy-2′,2′-difluorouridine). Plasma protein binding was minimal. In studies involving both short and long gemcitabine infusions, the pharmacokinetics were found to be linear and best described by a two-compartment model. Plasma half-life and clearance are influenced both by age and gender. For short infusions, half-lives varied from 32 to 94 minutes; for longer infusions, half-lives varied from 245 to 638 minutes. The volume of distribution was approximately 50 L/m^2 for short infusions and 370 L/m^2 for long infusions.

Preparation and Administration: Vials of gemcitabine contain 200 mg or 1 g of the HCl derivative formulated with mannitol (200 mg or 1 g) and sodium acetate (12.5 mg or 62.5 mg) as a sterile lyophilized powder. HCl or NaOH has been used for pH adjustment.

Toxic Effects: The major dose-limiting toxicity of gemcitabine is myelosuppression, although anemia and thrombocytopenia have also been encountered. Other toxicities include nausea and vomiting, transient elevations in liver function test results, mild hematuria, proteinuria (and in rare cases, hemolytic uremic syndrome), fever, rash, dyspnea, edema, and a flulike syndrome. Other infrequent toxicities included alopecia, paresthesias, and bronchospasm.

Potential Interactions: Gemcitabine may function as a radiosensitizing agent and can increase the toxicity of ionizing radiation. No other interactions are known.

Indications in Hematology: The primary indication for gemcitabine is in the treatment of patients with pancreatic carcinoma. However, as an experimental agent, gemcitabine is being evaluated for the treatment of acute lymphoblastic leukemia and chronic lymphocytic leukemia.

NELARABINE

Arabinofuranosylguanine (Ara-G)

Chemistry and Mechanism of Action: Nelarabine is a pro-drug of the deoxyguanosine analog 9′-β-D-arabinofuranosylguanine also known as ara-G. Accumulation of a metabolite ara-GTP in leukemic blasts allows for incorporation into deoxyribonucleic acid (DNA), leading to inhibition of DNA synthesis and cell death.

Absorption, Fate, and Excretion: Nelarabine is demethylated by adenosine deaminase (ADA) to ara-G; then monophosphorylated by deoxyguanosine kinase and deoxycytidine kinase; and subsequently converted to the active 5′-triphosphate, ara-GTP. Nelarabine is only available in an IV formulation. Nelarabine and ara-G are both partially eliminated by the kidneys. Approximately 5% to 10% of nelarabine is excreted by the kidneys compared with 20% to 30% of ara-G. Nelarabine exhibits a half-life of 30 minutes, and ara-G, the active metabolite, has a half-life of 3 hours.

Preparation and Administration: Nelarabine for injection is supplied as a clear, colorless, sterile solution in glass vials. Each vial contains 250 mg of nelarabine (5 mg of nelarabine per milliliter) and sodium chloride (4.5 mg/mL) in 50 mL of water for injection, USP. Nelarabine is not diluted before administration. The dose is transferred into polyvinylchloride (PVC) infusion bags or glass containers and administered as a 2-hour infusion in adult patients or as a 1-hour infusion in pediatric patients.

Toxic Effects: Bone marrow suppression encompassing all cell lines causing anemia, leucopenia, thrombocytopenia, and neutropenia occurs in all patients. Neurologic complications of nelarabine, include asthenia, altered mental states, including severe somnolence; central nervous system (CNS) effects, including convulsions, and peripheral neuropathy ranging from numbness and paresthesias to motor weakness and paralysis. Demyelinating disease of the CNS may occur when combining nelarabine with other drugs that may have CNS toxicity. Nausea and vomiting are seen and antiemetics are necessary.

Drug Interactions: Pentostatin has been shown to be a strong inhibitor of adenosine deaminase (ADA) in vitro. Concurrent administration of nelarabine and pentostatin may result in reduced ADA-dependent conversion of nelarabine to its active moiety, thereby potentially decreasing nelarabine efficacy or altering nelarabine's adverse event profile. Therefore, concomitant administration of nelarabine and pentostatin is not recommended.

Therapeutic Indications in Hematology: Nelarabine is effective in T-cell acute lymphoblastic leukemia, T-cell lymphoma, and T-cell lymphoblastic lymphoma. The dosage in adults of nelarabine is 1500 mg/m^2 administered intravenously over 2 hours on days 1, 3, and 5 repeated every 21 days. The pediatric dosage of nelarabine is 650 mg/m^2 administered intravenously over 1 hour daily for 5 consecutive days repeated every 21 days. The proper number of cycles for adult and pediatric patients has not been determined.

CLOFARABINE

Chemistry and Mechanism of Action: Clofarabine is a purine nucleoside antimetabolite formulated in unbuffered normal saline with a pH range of 4.5 to 7.5. It inhibits DNA synthesis by decreasing cellular deoxynucleotide triphosphate pools by inhibiting ribonucleotide reductase, terminating DNA chain elongation, and inhibiting repair through incorporation into the DNA chain by competitive inhibition of DNA polymerases.

Absorption, Fate, and Excretion: Clofarabine is 47% bound to plasma proteins, primarily albumin. Clofarabine is phosphorylated intracellularly to the cytotoxic active form (clofarabine triphosphate) by deoxycytidine kinase. The terminal half-life is estimated to be 5.2 hours with the metabolite clofarabine triphosphate, yielding a half-life greater than 24 hours, and 49% to 60% of the dose is excreted in the urine unchanged. Systemic clearance and volume of distribution at steady state were estimated to be 28.8 L/hr/m^2 and 172 L/m^2, respectively.

Preparation and Administration: Clofarabine is supplied in a 20-mL, single-use vial that contains 20 mg of clofarabine in 20 mL of unbuffered normal saline at a concentration of 1 mg/mL. Clofarabine should be filtered through a sterile 0.2-μm syringe filter and diluted with 5% dextrose injection, USP, or 0.9% sodium chloride injection, USP, before IV infusion to a final concentration between 0.15 and 0.4 mg/mL.

Toxic Effects: Bone marrow suppression encompassing all cell lines causing anemia, leucopenia, thrombocytopenia and neutropenia occurs in all patients. A capillary leak syndrome, also known as systemic inflammatory response syndrome (SIRS), thought related to cytokine release leading to respiratory distress, hypotension, pleural effusions, pericardial effusions, and multiorgan failure may occur in a small number of patients. Elevations of liver transaminases are seen and are transient (typically, less than 2 weeks' duration) and occurred within 1 week of clofarabine initiation. Elevations in bilirubin may also occur.

Drug Interactions: None described.

Therapeutic Indications in Hematology: Clofarabine is effective in treating acute lymphocytic leukemia. The recommended pediatric dose is 52 mg/m^2 administered by IV infusion over 2 hours daily for 5 consecutive days. Treatment cycles are repeated after recovery or return to baseline organ function, approximately every 2 to 6 weeks. Clofarabine has been used in adults at a dosage of 40 mg/m^2 administered by IV infusion over 2 hours daily for 5 consecutive days. Clofarabine has also been used in combination with cytarabine. Because this drug is excreted to a major extent by the kidneys, extreme caution should be used in patients with renal dysfunction.

APPENDIX 55-4

TOPOISOMERASE I INHIBITORS AND TOPOISOMERASE II INHIBITORS

TOPOISOMERASE II INHIBITORS

Etoposide (Vepesid), Etoposide Phosphate (Etopophos), Teniposide (Vumon)

Chemistry and Mechanism of Action: Etoposide (VP-16), etoposide phosphate, and teniposide (VM-26) are semisynthetic derivatives of epipodophyllotoxin. The mechanism of action of these drugs appears to be related to their ability to stabilize a topoisomerase II–DNA cleavable complex, which acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells.

Absorption, Fate, and Excretion: *Etoposide* has an oral bioavailability of 25% to 75%. Its terminal half-life is 6 to 8 hours, with approximately 30% to 40% excreted in the urine, two-thirds as unchanged drug. There is no accumulation with consecutive daily administration, but cytotoxicity has strict schedule dependency. Clinical studies suggest that in patients with a plasma creatinine level greater than 130 mol/L, the etoposide dose should be reduced by more than 25%.

Etoposide phosphate is rapidly and completely converted in vivo to VP-16 by the activity of phosphatase and has been shown to have the same pharmacokinetics as VP-16. Because of its increased water solubility, etoposide phosphate can be given intravenously in much less volume. In addition, the metabolic acidosis and hypotension seen with the infusion of VP-16 are not seen with this prodrug.

Teniposide has a multiphasic pattern of clearance from plasma with a terminal half-life of 9.5 to 21 hours. Unlike those of etoposide, metabolites of teniposide account for greater than 80% of the drug excreted in the urine. Similar to etoposide, there is significant interpatient and intrapatient variation in clinical pharmacokinetics. There are currently no formal recommendations for dose modification in patients with renal insufficiency.

Preparation and Administration: *Etoposide* is commercially available as 50-mg capsules and in vials of 50 and 100 mg at a concentration of 20 mg/mL. When the drug is diluted with normal saline or 5% dextrose in water to a concentration of 0.2 or 0.4 mg/mL, it is stable for 96 or 48 hours, respectively. Etoposide must be administered slowly over more than 30 minutes to prevent hypotension.

Etoposide phosphate is available commercially as single-dose vials containing etoposide phosphate equivalent to 100 mg of etoposide. When it is diluted with water, 5% dextrose, or normal saline to a concentration of 10 to 20 mg/mL, it can be administered without dilution over 5 to 10 minutes. When reconstituted, etoposide phosphate is stable for 24 hours at room temperature or under refrigeration.

Teniposide is supplied in 50-mg vials for IV use only. The IV solution may be taken orally but is unpalatable. Currently, no oral preparation is available in the market; however, for investigational purposes, each 50-mg vial may be dissolved in 50 to 100 mL of syrup or juice. To achieve optimal absorption, a single oral dose of 60 mg/m^2, which may be repeated at 6-hour intervals, is advised. As with etoposide, rapid infusion can produce hypotension.

Toxic Side Effects: Myelosuppression, especially leukopenia, is the dose-limiting toxic effect of *etoposide* and *teniposide*. Nausea and vomiting are usually mild and easily prevented with antiemetics. Rapid infusion of etoposide (<30 minutes) may cause hypotension. Anaphylactoid reactions (e.g., bronchospasm) occur in fewer than 2% of patients and may be related to the Cremophor vehicle. Alopecia occurs in approximately 20% of patients treated with etoposide. This side effect is more common with teniposide. When the drug is given in bone marrow transplantation doses, mucositis and diarrhea are prominent and may be dose limiting.

Potential Drug Interactions: Theoretically, any drug that increases the S-phase fraction will increase the cytotoxicity of epipodophyllotoxins and other topoisomerase inhibitors. Conversely, drugs that inhibit DNA synthesis antagonize the effect of *etoposide* and *teniposide* (e.g., 5-fluoro-2′-deoxyuridine given before etoposide in some human cancer cell lines decreases the cytotoxicity of the latter). More recent in vitro data suggest that synergistic cytotoxic effects are seen when VP-16 is given after a topoisomerase I inhibitor, which appears to upregulate the amount of topoisomerase II enzyme. Antagonistic effects have been reported when a topoisomerase II inhibitor is given before a topoisomerase I inhibitor. In hematology, etoposide and teniposide may inhibit the intracellular ara-CTP formation leading to reduced ara-C cytotoxicity. Potentiation of teniposide activity has been seen with methotrexate and dipyridamoles. There is at least a twofold increase in the clearance of teniposide with concomitant administration of phenobarbital or phenytoin. Cyclosporine and other P-glycoprotein antagonists (PSC 833) potentiate the cytotoxic effects of etoposide.

Therapeutic Indications: *Etoposide* is used in the treatment of non-Hodgkin lymphoma (NHL) and as a second-line treatment for Hodgkin disease. It is also incorporated in the preparatory regimens for bone marrow transplantation of refractory lymphomas (CBV) and acute leukemia. *Teniposide* has been approved as a front-line agent with combination chemotherapy for childhood acute lymphoblastic leukemia (ALL). Combination chemotherapy with teniposide has been used successfully in some cases of refractory adult ALL and acute monocytic leukemia, but the duration of remission is not significantly different from that with other standard salvage regimens. In NHL, teniposide has shown comparable activity to vincristine. *Etoposide phosphate* has been given in both standard-dose and high-dose (as a single agent) chemotherapy regimens and appears to have the same pharmacokinetics and antitumor activity as VP-16.

Daunorubicin

Chemistry and Mechanism of Action: Daunorubicin is an anthracycline that inhibits DNA topoisomerase II, acting as a poison at lower concentrations and a suppressor of cleavable complex formation at higher doses. Daunorubicin is also a DNA intercalator and generates reactive oxygen intermediates.

Absorption, Fate, and Excretion: After IV injection, daunorubicin undergoes rapid tissue uptake and concentration. It is rapidly metabolized in the liver, where approximately 25% of the drug concentrates and has a half-life of 20 to 50 hours. The principal metabolite is daunorubicinol, which also displays antineoplastic activity. Biliary excretion accounts for approximately 75% of the drug and metabolite elimination. Patients with significant hepatic dysfunction should receive an attenuated dose of daunorubicin.

Preparation and Administration: Daunorubicin is supplied with 100 mg of mannitol in 20-mg vials, from which it is

reconstituted with 4 mL of sterile water for injection. The vial should be protected from sunlight. Daunorubicin is a powerful vesicant that should be administered into the tubing of a freely flowing IV infusion of either 5% dextrose in water or normal saline. In the event of extravasation, as much infiltrated drug as possible should be aspirated from the tissue, and cold compresses should be maintained on the site for several hours. Despite these measures, skin grafting may be necessary. Daunorubicin is not physically compatible with heparin, and the two drugs should not be coadministered in the same IV tubing. The patient should be informed that daunorubicin may impart a red color to the urine for up to 72 hours after administration.

Toxic Effects: Myelosuppression, predominantly leukopenia, is the dose-limiting toxic effect. Mucositis, nausea and vomiting, and alopecia are common. Facial flushing, conjunctivitis, and lacrimation may occur in rare cases. Erythematous streaking near the site of injection occurs as a benign local allergic reaction and should not be confused with extravasation. The drug can produce a severe local reaction (e.g., pneumonitis, esophagitis) in previously irradiated areas, even when both therapies are not administered concomitantly (radiation recall). Cardiac toxicity is a unique characteristic of the anthracycline antibiotics and can be acute or chronic. In the acute form, abnormal ECG changes such as ST-T wave elevation and arrhythmias may be seen. Transient reduction in the ejection fraction can also occur acutely and is often associated with pericarditis (pericarditis-myocarditis syndrome). The chronic form of anthracycline cardiac toxicity is related to the cumulative dose. The dose limit of doxorubicin is generally considered to be 450 to 500 mg/m^2, where the risk of clinical cardiotoxicity is between 1% and 10%. The corresponding cumulative dose limit for daunorubicin is 900 to 1000 mg/m^2. The cardiac toxicity is clinically characterized by congestive heart failure, usually refractory to medical therapy. Cardiac irradiation or the administration of cyclophosphamide may increase the risk of cardiotoxicity. The cardiotoxic effects appear to be related to the formation of free radicals and not to the inhibition of DNA topoisomerase II. The cardioprotective agent dexrazoxane (Zinecard) is now available and recommended to be started at a doxorubicin cumulative dose greater than 350 mg/m^2.

Potential Drug Interactions: Daunorubicin is not physically compatible with heparin or dexamethasone. The drug interactions described for doxorubicin (description follows) probably occur with daunorubicin as well.

Therapeutic Indications in Hematology: Daunorubicin is used in combination with other drugs in the treatment of acute myeloid leukemia and ALL.

Doxorubicin (Adriamycin)

Chemistry and Mechanism of Action: Doxorubicin is also an anthracycline glycoside antibiotic. It differs from daunorubicin at C-8, in which a hydroxyacetyl group replaces an acetyl group. Because of this, doxorubicin is also called hydroxyl daunorubicin. Its mechanisms of action also involve stabilizing DNA–topoisomerase II complexes, DNA intercalation, and free radical formation.

Absorption, Fate, and Excretion: Doxorubicin has a triphasic plasma clearance with a half-life of approximately 30 hours. The drug is extensively metabolized in the liver to yield an active metabolite (doxorubicinol) and a number of inactive metabolites (aglycones). Within 7 days, more than 50% of an injected dose is excreted in the bile, but only 5% to 10% of the drug is excreted in the urine. Penetration into the cerebrospinal fluid is poor.

Preparation and Administration: Doxorubicin is commercially available in vials of 10, 20, 50, 150, and 200 mg. The lyophilized powder is reconstituted with either normal saline or sterile water for injection to yield a 2-mg/mL solution. The reconstituted solution must be protected from sunlight. The drug should be injected slowly into the tubing of a freely running IV infusion of normal saline or 5% dextrose in water. Erythematous streaking along the vein is often an indication that the administration rate is too rapid. The drug is a powerful vesicant, and in case of extravasation, the measures described for daunorubicin should be followed.

Toxic Effects: The toxic effects are similar to those of daunorubicin. It is important to emphasize that weekly low-dose regimens or administration by continuous infusion can decrease the risk of cardiotoxicity with doxorubicin.

Potential Drug Interactions: When used in combination with other drugs as treatment for leukemia or lymphoma, doxorubicin may decrease the oral bioavailability of digoxin. It is not physically compatible with heparin or 5-fluorouracil. Barbiturates may increase the plasma clearance of doxorubicin and decrease its cytotoxic effect. Doxorubicin is compatible with vincristine, and the two drugs can be administered together in the same IV solution.

Therapeutic Indications in Hematology: Doxorubicin is one of the most important drugs in the treatment of hematologic malignancies. It is used in the treatment of Hodgkin disease (ABVD regimen), non-Hodgkin lymphoma (CHOP, MACOP-B), and multiple myeloma (VBAP, VAD).

Idarubicin (Idamycin)

Chemistry and Mechanism of Action: Idarubicin, also called 4′-demethoxydaunorubicin (4-DMDR), is an analog of daunorubicin in which the methoxy group from the aglycone has been replaced with hydrogen. Idarubicin is also a topoisomerase II inhibitor and generates free radicals.

Absorption, Fate, and Excretion: The elimination half-life of the parent compound is 11.3 hours and that of the primary metabolite, 13-epirubicinol, is 40 to 60 hours. The major metabolite is as active as idarubicin. The oral bioavailability of this drug is approximately 30%; 80% of the drug is excreted in the urine as 13-epirubicinol.

Preparation and Administration: Idarubicin is supplied in 5- and 10-mg vials from which it is reconstituted with sterile water or normal saline to obtain a 1 mg/mL solution. The drug should be infused from 10 to 15 minutes through the tubing of a freely running IV infusion. Extravasation precautions should be instituted during administration. The oral formulation remains investigational.

Toxic Effects: The side effects of idarubicin are similar to those of daunorubicin and doxorubicin but are of lesser intensity at equal myelosuppressive doses.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Idarubicin in combination with ara-C is equivalent, if not superior, to combination chemotherapy with daunorubicin in the treatment of adult acute myeloid leukemia (AML) and myelodysplastic syndromes. Idarubicin has been approved for use in combination therapy for adult AML.

Mitoxantrone (Novantrone)

Chemistry and Mechanism of Action: Mitoxantrone is a synthetic anthracenedione. Its mechanism of action appears to involve primarily the inhibition of DNA topoisomerase II. Its reduced potential for free radical formation may explain the decreased cardiotoxicity of this drug.

Absorption, Fate, and Excretion: Mitoxantrone is excreted via the renal and hepatobiliary systems, but the hepatobiliary elimination accounts for approximately 30% of active drug elimination and

appears to be of greater importance. The half-life is quite variable, with a range of 23 to 42 hours. Patients with severe hepatic dysfunction have been shown to eliminate the drug more slowly.

Preparation and Administration: Mitoxantrone is commercially available as a 2 mg/mL solution in 10-mL, 12.5-mL, and 15-mL vials (20, 25, and 30 mg per vial, respectively). The drug is further diluted in normal saline or 5% dextrose in water for injection and is administered for approximately 15 to 30 minutes into the tubing of a freely running IV infusion. As with the anthracyclines, erythema or streaking along the vein of infusion indicates that the drug is being infused too rapidly. Although mitoxantrone is not a vesicant, there have been rare reports of tissue necrosis after extravasation.

Toxic Effects: Myelosuppression, principally leukopenia, is the dose-limiting toxic effect. Thrombocytopenia is relatively mild. Nausea, vomiting, and alopecia are usually mild and occur in fewer than 30% of patients treated. Rarely, mucositis and elevation of liver enzymes occur. The drug imparts a blue color to the urine of patients treated. One of the primary advantages of mitoxantrone, compared with doxorubicin, is its reduced incidence of cardiac toxicity. Occasionally, patients develop congestive heart failure after treatment with mitoxantrone in the absence of prior anthracycline exposure, although the incidence appears to be less than 5%.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Mitoxantrone is approved for induction therapy of acute myeloid leukemia in adults.

Amsacrine

Chemistry and Mechanism of Action: Amsacrine, or 4′-(9-acridinylamino) methanesulfon-*m*-anisidide (AMSA) is a synthetic aminoacridine derivative. Amsacrine is a DNA intercalator and inhibits the activity of DNA topoisomerase II.

Absorption, Fate, and Excretion: When given intravenously, this drug has an initial half-life of 30 minutes and a terminal half-life of 7.9 hours. It is 50% protein bound after 2 hours. It is metabolized by conjugation with glutathione, and approximately 50% of the drug is eliminated in the bile. The remainder of the drug is eliminated via the urinary route as metabolites and parent drug.

Preparation and Administration: Amsacrine is an investigational agent supplied by the National Cancer Institute as a group C drug. It is provided in a dual pack containing two sterile liquids that must be combined before use. One vial contains 1.5 mL of 50 mg/mL of AMSA in anhydrous *N*,*N*-dimethylactamide, and the other contains 13.5 mL of 0.0353 mL lactic acid diluent. When these are combined, the resulting orange-red solution contains 5 mg/mL of AMSA. Because of the *N*,*N*-dimethylactamide solvent, plastic syringes should not be used with the undiluted AMSA solution.

Toxic Effects: The dose-limiting toxic effect is myelosuppression, predominantly affecting granulocytes. Alopecia is common, and nausea, vomiting, and mucositis can occur. Cardiotoxicity, manifested as a decrease in ejection fraction, acute arrhythmias, or electrocardiographic changes was reported in 2.3% of 3200 patients, but most of these patients had been heavily pretreated with anthracyclines. Hypokalemia seems to enhance amsacrine cardiotoxicity and if present should be corrected before administration of the drug.

Potential Drug Interactions: The reconstituted solution is physically incompatible with chloride-containing solutions.

Therapeutic Indications in Hematology: Amsacrine is a group C investigational drug approved for the treatment of refractory acute myeloid leukemia, although it is being evaluated in combination with other cytotoxic agents in the initial treatment of this disease. As a group C drug, amsacrine must be administered as a single agent.

TOPOISOMERASE I INHIBITORS

Topotecan (Hycamtin)

Chemistry and Mechanism of Action: Topotecan is a semisynthetic derivative of camptothecin that stabilizes a complex between DNA topoisomerase I and DNA. The cytotoxic effect of this drug is believed to result from the collision of DNA replication forks with a ternary complex of topoisomerase I, DNA, and topotecan. The resulting double-strand DNA breaks are lethal. The lactone form of topotecan, which predominates at an acidic pH, is a much more potent inhibitor of DNA topoisomerase I.

Absorption, Fate, and Excretion: At neutral or physiologic pH, the carboxylate form of topotecan is favored, and at a pH of less than 7, the lactone form is favored. Topotecan has been given as a bolus or by continuous infusion. In less than 1 hour after infusion, most of the circulating drug in the plasma is in the carboxylate form as a result of the physiologic pH. Whereas the terminal half-life of the lactone form of this S phase–specific agent is 2.6 hours, the terminal half-life of the total drug is 3.3 hours. In an IV dose, 36% is excreted unchanged in the urine, and there is a 1.5-fold concentration of the drug in bile. Cerebrospinal fluid levels of topotecan lactone reach approximately 32% of plasma levels. Dose adjustment is required for a creatinine clearance less than 60 mL/min, but no adjustment is necessary for a bilirubin up to 10 mg/dL.

Preparation and Administration: Topotecan is commercially available as 4-mg vials that are reconstituted with 4 mL of sterile water. This solution can be further diluted in normal saline or 5% dextrose in water and should be used immediately.

Toxic Effects: The dose-limiting toxicity for topotecan for all schedules is neutropenia. Thrombocytopenia and anemia are less common, although there is an increase in thrombocytopenia with continuous infusion schedules. Other less common and mild toxicities include nausea, vomiting, diarrhea, fever, fatigue, alopecia, skin rash, and increased liver function tests. Mucositis has been seen with prolonged infusion schedules over 5 days or when topotecan is given in higher doses.

Potential Drug Interactions: In vitro data suggest that there may be some synergism if a topoisomerase I inhibitor is given before a topoisomerase II inhibitor. In vitro data also suggest that synergism may be seen if a topoisomerase I inhibitor (topotecan) is given after an alkylating agent, suggesting that topoisomerase I may be involved in the repair of alkylator-induced DNA damage.

Therapeutic Indications in Hematology: Phase II studies suggest that topotecan has activity in myelodysplastic syndromes, acute myeloid leukemia, and multiple myeloma.

Irinotecan (Camptosar or CPT-11)

Chemistry and Mechanism of Action: CPT-11 is a prodrug that has a bulky piperidino side chain at C-10 that is cleaved in vivo by a carboxylesterase-converting enzyme to generate SN-38. SN-38 is approximately 1000-fold more potent a topoisomerase I inhibitor than CPT-11. The lactone forms of both SN-38 and CPT-11 are more potent inhibitors of topoisomerase I than the carboxylate forms, which is felt to be the mechanism of action of these drugs as described for topotecan.

Absorption, Fate, and Excretion: The terminal half-life of the lactone form of CPT-11 is 7 hours, and that of the total drug is 10.5

hours. The terminal half-life of SN-38 lactone is 8.7 hours, and that of the total drug is 14.7 hours. Of a dose of irinotecan, 22% is excreted unchanged in the urine. SN-38 is excreted into the bile and can undergo glucuronidation. Whereas the plasma protein binding of CPT-11 is reported to be between 30% and 68%, that of SN-38 is 95%.

Preparation and Administration: Irinotecan is available as a 100-mg single-dose vial with 20 mg/mL of irinotecan. This preparation also contains 45 mg of sorbitol per milliliter and 0.9 mg of lactic acid per milliliter with the pH adjusted to 3.5. This solution can be diluted with 5% dextrose in water (preferred) or in normal saline to a final concentration of 0.1 to 1.2 mg/mL. The solution is stable for up to 24 hours at room temperature or 48 hours when refrigerated. The dose should be modified for severe diarrhea.

Toxic Effects: The major toxic effect of irinotecan is diarrhea. This can be early-onset diarrhea, occurring within hours of administration, or during the infusion, which can be associated with cramping, vomiting, flushing, and diaphoresis. These side effects are attributable to the cholinergic effects of CPT-11 and can be managed with atropine. Severe later onset diarrhea can be treated with high-dose loperamide, which has been found to decrease the incidence of grade 4 diarrhea from 20% to 2%. Diarrhea has been found to be the dose-limiting toxicity when irinotecan is given on a weekly schedule, and neutropenia is the dose-limiting toxicity when the drug is given every 3 weeks. Also seen are alopecia, nausea, vomiting, mucositis, fatigue, increased liver function test results, and rare cases of pulmonary toxicity.

Potential Drug Interactions: As described for topotecan, in vitro data suggest some synergism when topoisomerase I inhibitors precede topoisomerase II inhibitors or follow alkylating agent administration.

Therapeutic Indications in Hematology: Phase I and phase II studies have shown responses in refractory leukemia and lymphoma.

APPENDIX 55-5

CLINICAL PHARMACOLOGY OF PLATINUM ANALOGS

CISPLATIN (PLATINOL)

Chemistry and Mechanism of Action: Cisplatin [cisdiamined ichloroplatinum(II)] is an inorganic heavy metal complex. This complex can have *cis*- and *trans*-isomers; the *cis*-isomer is the active antitumor drug. In the relatively higher chloride concentrations of plasma, cisplatin is uncharged in the dichloroform and passes through plasma membranes. Intracellularly, the low chloride concentrations allow the displacement of the chloride ligands by water to form the positively charged aquated complex. This forms covalent cross-links between two nucleophilic atoms of macromolecules such as the N^7 positions of guanine and adenine in DNA. The cytotoxicity of cisplatin correlates closely with total platinum binding to DNA, to interstrand cross-links and to the formation of intrastrand bidentate N^7 adducts at d(GpG) and d(ApG), resulting in intrastrand cross-links that bend the DNA helix and inhibit DNA synthesis. Cisplatin damage to DNA induces apoptosis of sensitive cells.

Absorption, Fate, and Excretion: After IV injection, the drug concentrates in the liver, kidneys, and bowel. Plasma levels of cisplatin decay in a biphasic manner, with an initial half-life of 25 to 49 minutes and a terminal half-life of 58 to 73 hours. Although 15% of the administered cisplatin is excreted unchanged in the urine, up to 90% of the administered dose of the drug can be recovered from the urine.

Preparation and Administration: Cisplatin is commercially available as a lyophilized powder, supplied in 10- and 50-mg vials also containing mannitol, sodium chloride, and hydrochloric acid and as an aqueous solution in 50- and 100-mg vials. Reconstitution of the powder for injection is achieved by adding sterile water to make a 1-mg/mL solution. The reconstituted solution should be further diluted in normal saline (usually 500 mL to 1 L) and administered over 1 to 3 hours. To prevent nephrotoxic effects, 25 to 50 g of mannitol is often added to the saline solution, and patients are aggressively hydrated before and after cisplatin infusion. Magnesium sulfate (12-24 mEq) is commonly added to the saline solution to preclude the development of hypomagnesemia.

Toxic Effects: Nephrotoxicity is the dose-limiting toxic effect. Cisplatin produces a dose-dependent impairment of renal tubular function manifested by an increase in serum creatinine as well as potassium and magnesium wasting. The renal dysfunction is usually reversible, but repeated treatments may produce a cumulative and permanent mild to moderate impairment of renal function. Administration of other nephrotoxic agents such as aminoglycosides, even between courses, can potentiate its toxicity. Nausea and vomiting are usually severe and require the use of aggressive antiemetic support. When doses greater than 70 mg/m^2 are used, it is also important to protect against delayed nausea and vomiting by administering antiemetic agents (e.g., prochlorperazine plus dexamethasone) for 3 days after therapy. Myelosuppression is usually mild. High-frequency hearing loss, tinnitus, and frank deafness may occur. Peripheral neurotoxicity, characterized by paresthesias or sensory loss in a glove-and-stocking distribution or as muscular weakness, is relatively common in patients who receive total cumulative doses of greater than 500 mg/m^2. The peripheral neuropathy may take many months to resolve, if it does at all. Vestibular toxicity and anaphylactic reactions may occur rarely.

Potential Drug Interactions: Aminoglycosides and amphotericin may enhance cisplatin nephrotoxicity. Caution should be exercised when cisplatin is administered with bleomycin and methotrexate because cisplatin-induced renal damage may delay the excretion and thus increase the toxicity of these agents.

Therapeutic Indications in Hematology: Cisplatin is used in the treatment of refractory lymphomas, usually in combination with ara-C and high-dose dexamethasone.

CARBOPLATIN (PARAPLATIN)

Chemistry and Mechanism of Action: Carboplatin is a second-generation platinum (II) complex. Its mechanism of action is very similar to that of cisplatin. However, the carboxyl ester groups in this platinum complex are less easily displaced and less chemically reactive. The peak levels of DNA cross-linking also occur 6 to 12 hours later for carboplatin than for cisplatin.

Absorption, Fate, and Excretion: Carboplatin is primarily eliminated through the kidneys. Its elimination is slower than cisplatin with a terminal half-life between 2 and 6 hours. After IV injection, approximately 60% of the total drug is excreted within 24 hours.

Preparation and Administration: Carboplatin is commercially available as a lyophilized powder in 50- and 150-mg vials containing carboplatin and mannitol. It is reconstituted with sterile water to a final concentration of 10 mg/mL. For injection, further dilution with 5% dextrose and water or normal saline to a concentration of 0.5 or 2 mg/mL, in which it is stable for 8 hours at room temperature. Carboplatin is often administered by IV injection over 15 to 30 minutes. Patients with reduced renal function (creatinine clearance of <60 mL/min) should have the dose of carboplatin decreased according to the formula described by Egorin et al.

For previously untreated patients:

$$\begin{aligned}\text{Dosage (mg/m}^2\text{)} &= (0.091)(\text{Creatinine clearance/Body surface area}) \\ &\times [\text{Pretreatment platelet count} - \text{Platelet nadir desired/Pretreatment platelet count} \times 100] + 86\end{aligned}$$

For heavily pretreated patients:

$$\begin{aligned}\text{Dosage (mg/m}^2\text{)} &= (0.091)(\text{Creatinine clearance/Body surface area}) \\ &\times [(\text{Pretreatment platelet count} - \text{Platelet nadir desired/Pretreatment platelet count} \times 100) - 17] + 86\end{aligned}$$

A formula developed by Calvert and colleagues also takes into account the patient's pretreatment renal function, as follows:

$$\text{Dose (mg)} = \text{Target AUC (mg/mL} \times \text{min)} \times [\text{GFR (mL/min)} + 25]$$

where the dose in mg (not mg/m^2 body surface area) equals target AUC (area under the plasma clearance curve) × GFR (glomerular filtration rate) + 25.

In previously untreated adults, the AUC can be estimated at 7 when carboplatin is used alone and 4.5 when used in combination. If AUC is set lower, less toxicity is expected.

Toxic Effects: The dose-limiting toxic effect is myelosuppression, thrombocytopenia being more significant than leukopenia. Carboplatin leads to less emesis than cisplatin. Although nausea and vomiting are common, they can be easily controlled with antiemetics. At high doses such as those used for bone marrow transplantation, hepatotoxicity, renal dysfunction, and moderate to severe cytotoxicity can occur.

Potential Drug Interactions: None reported.

Clinical Indications in Hematology: Carboplatin has been recently approved for the treatment of ovarian cancer. It is also used to treat small cell lung, testicular, head and neck, and genitourinary cancers. High-dose carboplatin is presently under evaluation in acute leukemias and lymphomas.

APPENDIX 55-6

CLINICAL PHARMACOLOGY OF MISCELLANEOUS AGENTS

THALIDOMIDE

Chemistry and Mechanism of Action: The mechanism of action of thalidomide is not fully understood. Thalidomide has immunomodulatory, antiinflammatory, and antiangiogenic properties. The immunologic effects vary substantially under differing conditions but seem to suppress tumor necrosis factor-α production and downmodulate cell surface adhesion molecules. Other antiinflammatory and immunomodulatory properties include suppression of macrophage involvement in prostaglandin synthesis and modulation of interleukin-10 and interleukin-12 production by peripheral blood mononuclear cells. Angiogenesis inhibition is described, but the exact mechanism is not yet definitively defined.

Absorption, Fate, and Excretion: Thalidomide absorption is slow after oral administration, and the bioavailability of capsules has not yet been determined, but based on radiolabeled thalidomide, greater than 90% is recovered in urine, suggesting good oral absorption. The mean elimination half-life of thalidomide ranges from 3 to 6.7 hours, but the exact metabolic fate of thalidomide is unknown. Protein binding is 55% to 66%.

Preparation and Administration: Thalidomide is available as 50-, 100-, 150-, and 200-mg oral capsules. A 20-mg/mL oral suspension may be prepared with capsules and a 1 : 1 mixture of Ora-Sweet and Ora-Plus by emptying the contents of twelve 100-mg capsules into a glass mortar. Add small portions of the vehicle and mix to a uniform paste; mix while adding the vehicle in incremental proportions to almost 60 mL; transfer to an amber calibrated bottle and add quantity of vehicle sufficient to make 60 mL. Stable for 35 days refrigerated.

Toxic Effects: Thalidomide frequently may cause deep venous thrombosis and pulmonary embolism. Thalidomide causes birth defects in humans. It must not be given during pregnancy. Leucopenia along with thrombocytopenia is observed. Pruritus and rash as well as constipation are seen.

Drug Interactions: Thalidomide increases cyclosporine A metabolism and clearance. An increase in the thrombogenic state in patients with myelodysplastic syndrome (MDS) has been observed in patients receiving darbepoetin alfa and thalidomide. The addition of docetaxel to thalidomide increases the risk of venous thromboembolism.

Therapeutic Indications in Hematology: Thalidomide has been used to treat multiple myeloma and MDS.

LENALIDOMIDE

Chemistry and Mechanism of Action: Lenalidomide, a thalidomide analog, is an immunomodulatory agent with antineoplastic and antiangiogenic activity. Lenalidomide affects ligand-induced responses (angiogenesis, inflammation, cell adhesion, immune response), inhibits production of tumor necrosis factor, increases production of interleukin-2 and interferon-γ, and increases cytolytic T-cell and natural killer (NK) cell responses. It inhibits trophic signals to angiogenic factors in cells. and inhibits growth of myeloma cells by inducing cell cycle arrest and apoptosis.

Absorption, Fate, and Excretion: Lenalidomide is rapidly absorbed after oral administration. Lenalidomide has a half-life of 3 hours with 67% of the drug excreted unchanged in the urine. Adjustment to the initial dosage is recommended in patients with moderate or severe renal impairment. Compared with patients with normal renal function, those with moderate and severe renal impairment have a 66% to 75% decrease in drug clearance, and patients on hemodialysis have an 80% decrease in clearance. Although the drug is 30% protein bound, lenalidomide is partially removed by hemodialysis and should be given after dialysis. Food does not alter the extent of absorption nor the AUC of lenalidomide.

Preparation and Administration: Lenalidomide is available in 2.5-, 5-, 10-, 15-, and 25-mg capsules for oral administration. Each capsule contains lenalidomide as the active ingredient along with lactose anhydrous, microcrystalline cellulose, croscarmellose sodium, and magnesium stearate.

Toxic Effects: Lenalidomide frequently may cause deep venous thrombosis and pulmonary embolism. Severe myelosuppression across all cell lines is common. Pruritus and rash as well as constipation and hypokalemia are seen. Lenalidomide is an analogue of thalidomide and may cause birth defects in humans. It must not be given during pregnancy.

Drug Interactions: Lenalidomide increases digoxin plasma concentrations. Dexamethasone increases the thrombogenic effect of Lenalidomide.

Therapeutic Indications in Hematology: Lenalidomide has activity in multiple myeloma when used in combination with dexamethasone, Chronic lymphoid leukemia as well myelodysplastic syndrome with deletion 5q abnormality. It also has shown some efficacy in myelofibrosis and refractory non-Hodgkin lymphoma.

POMALIDOMIDE

Chemistry and Mechanism of Action: Pomalidomide is structurally and functionally related to thalidomide. Its mechanism is not fully understood but has effects on angiogenesis, alters inflammatory and regulatory cytokines, and may affect T cells.

Absorption, Fate, and Excretion: Pomalidomide is administered orally. Pharmacokinetic data are still being elucidated.

Preparation and Administration: Pomalidomide is an investigational agent administered orally.

Toxic Effects: Pomalidomide has extensive bone marrow toxicity affecting all three cell lines, peripheral neuropathy, orthostasis, rashes, pulmonary toxicity and clotting abnormalities.

Drug Interactions: Data not available.

Therapeutic Indications in Hematology: Pomalidomide has been studied in multiple myeloma.

TEMSIROLIMUS

Chemistry and Mechanism of Action: Temsirolimus is an inhibitor of mTOR (mammalian target of rapamycin) and binds to an intracellular protein (FKBP-12). This protein–drug complex inhibits the activity of mTOR and results in G1 growth arrest. When mTOR is inhibited, its ability to phosphorylate p70S6k and S6 ribosomal protein, which are downstream of mTOR in the PI3 kinase/AKT pathway, was blocked.

Absorption, Fate, and Excretion: Temsirolimus is predominately metabolized in human liver microsomes by cytochrome P450 3A4 (CYP3A4). Temsirolimus is extensively metabolized to sirolimus. Four other metabolites account for less than 10% in the plasma. The mean half-life of temsirolimus is 17.3 hours, and the mean half-life of sirolimus, the active metabolite, is 54.6 hours. Neither the parent drug nor its metabolite is dialyzable. Dosage reduction or discontinuance may be warranted in patients with hepatic impairment to reduce the potential for toxicity.

Preparation and Administration: Temsirolimus is supplied as a kit consisting of 2 vials, temsirolimus injection (25 mg/mL) and a diluent of 1.8 mL. Temsirolimus is mixed with 1.8 mL of the diluent. The resultant solution contains 10 mg/mL The concentrate–diluent mixture is stable below 25° C for up to 24 hours. To administer, withdraw the required amount of concentrate–diluent mixture and further dilute into an infusion bag containing 250 mL of 0.9% sodium chloride injection, USP. Patients should receive prophylactic IV diphenhydramine 25 mg before the start of each dose.

Toxic Effects: Temsirolimus causes a decreased lymphocyte count, leucopenia, decreased hemoglobin, and thrombocytopenia. Hyperglycemia, edema, and rash (which may progress to Stevens-Johnson syndrome) have also been seen.

Drug Interactions: The concomitant use of strong CYP3A4 inhibitors (e.g., ketoconazole, itraconazole, clarithromycin, atazanavir, indinavir, nefazodone, nelfinavir, ritonavir, saquinavir, telithromycin, and voriconazole) may increase plasma concentrations of sirolimus (a major metabolite of temsirolimus). The use of concomitant strong CYP3A4 inducers (e.g., dexamethasone, phenytoin, carbamazepine, rifampin, rifabutin, rifampicin, phenobarbital) may decrease plasma concentrations of sirolimus (a major metabolite of temsirolimus).

Therapeutic Indications in Hematology: Temsirolimus has been shown to have activity in mantle cell lymphoma.

EVEROLIMUS

Chemistry and Mechanism of Action: Everolimus is an analogue of rapamycin (sirolimus) with immunosuppressive and antiproliferative activity. Everolimus is an inhibitor of rapamycin (mTOR), a serine-threonine kinase, downstream of the PI3K/AKT pathway. After binding and forming a complex with the cytoplasmic FK506–binding protein 12 (FKBP-12), the complex binds to and inhibits the mammalian mTOR and phosphorylates P70 S6 ribosomal protein kinase (a substrate of mTOR). Everolimus reduces the activity of S6 ribosomal protein kinase (S6K1) and eukaryotic elongation factor 4E–binding protein (4E-BP1). In addition, everolimus inhibits the expression of hypoxia-inducible factor 1 and reduces the expression of vascular endothelial growth factor.

Absorption, Fate, and Excretion: Peak everolimus concentrations are reached 1 to 2 hours after oral administration with protein binding of 74%. Everolimus is extensively metabolized by the liver with everolimus being a substrate of CYP3A4 and P-glycoprotein. Metabolism involves demethylation, hydroxylation, and ring degradation. There are six main metabolites of everolimus, which have approximately 100 times less activity than the parent everolimus compound, including three monohydroxylated metabolites, two hydrolytic ring-opened metabolites, and a phosphatidylcholine conjugate of everolimus. The elimination half-life is 30 hours and is prolonged to a mean of 79 hours in patients with moderate hepatic impairment.

Preparation and Administration: Everolimus is available in 2.5-, 5-, 7.5- and 10-mg nonscored tablets.

Toxic Effects: Everolimus causes bone marrow suppression across all cell lines, hyperglycemia, rash, and mucositis along with pulmonary toxicity.

Drug Interactions: Everolimus concentrations are increased when administered with CYP3A4 or P-glycoprotein Inhibitors such as ketoconazole, itraconazole, clarithromycin, atazanavir, nefazodone, saquinavir, telithromycin, ritonavir, indinavir, nelfinavir, voriconazole, amprenavir, fosamprenavir, aprepitant, erythromycin, fluconazole, verapamil, diltiazem, grapefruit, grapefruit juice, or St. John's wort. Everolimus concentrations are decreased when administered with strong CYP3A4 inducers such as phenytoin, carbamazepine, rifampin, rifabutin, rifapentine, or phenobarbital.

Therapeutic Indications in Hematology: Everolimus has been used in mantle cell lymphoma, diffuse large B-cell lymphoma, and Hodgkin lymphoma.

ARSENIC TRIOXIDE

Chemistry and Mechanism of Action: The mechanism of action of arsenic trioxide is not completely understood. Arsenic trioxide causes morphologic changes and DNA fragmentation characteristic of apoptosis in NB4 human promyelocytic leukemia cells in vitro possibly mediated by activation of cysteine-proteases (caspases). Arsenic trioxide also causes damage or degradation of the fusion protein PML/RARβ.

Absorption, Fate, and Excretion: The metabolism of arsenic trioxide involves reduction of pentavalent arsenic to trivalent arsenic by arsenate reductase and methylation of trivalent arsenic to monomethylarsinic acid and monomethylarsinic acid to dimethylarsinic acid by methyltransferases. The main site of methylation reactions appears to be the liver. The pharmacokinetics of trivalent arsenic, the active species, have not been characterized.

Preparation and Administration: Arsenic trioxide is available in 10-mL, single-use ampules containing 10 mg of arsenic trioxide. It is formulated as a sterile, nonpyrogenic, clear solution of arsenic trioxide in water for injection using sodium hydroxide and dilute hydrochloric acid to adjust to pH 8. Trisenox should be diluted with 100 to 250 mL of 5% dextrose injection, USP, or 0.9% sodium chloride injection, USP. Arsenic trioxide should be administered intravenously over 1 to 2 hours. The infusion duration may be extended up to 4 hours if acute vasomotor reactions are observed. A central venous catheter is not required.

Toxic Effects: Arsenic trioxide has electrocardiographic abnormalities, including QT interval prolongation, T-wave flattening, and atrioventricular block. Nonspecific edema and weight gain have been reported. Dry skin, pruritus, and rashes have occurred relatively frequently. Anemia, thrombocytopenia, and neutropenia are also observed.

Drug Interactions: Arsenic trioxide can cause QT interval prolongation and complete atrioventricular block. QT prolongation can lead to a torsade de pointes–type ventricular arrhythmia. The risk of torsade de pointes is related to the extent of QT prolongation, and concomitant administration of QT-prolonging drugs may exacerbate this phenomenon.

Therapeutic Indications in Hematology: Arsenic trioxide is effective in newly diagnosed acute promyelocytic leukemia, FAB M3.

Moreover, in patients who are refractory to or have relapsed from retinoid and anthracycline chemotherapy, arsenic trioxide has some activity as a single agent for relapsed or refractory multiple myeloma. Arsenic trioxide produced hematologic improvement in a subset of patients with myelodysplastic syndrome.

BORTEZOMIB (VELCADE)

Molecular Formula: The mlecular formula is $C_{19}H_{25}BN_4O$ molecular weight 384.24 g/mol bortezomib (*N*-pyrazinecarbonyl-L-phenylalanine-L-leucine boronic acid).

Absorption, Fate, and Excretion: After IV administration of 1.3 mg/m^2 dose, the median estimated maximum plasma concentration of bortezomib was 509 ng/mL (range, 109-1300 ng/mL). The mean elimination half-life of bortezomib after first dose ranged from 9 to 15 hours at doses ranging from 1.45 to 2.00 mg/m^2 in patients with advanced malignancies. In vitro studies with human liver microsomes and human cDNA-expressed cytochrome P450 isozymes indicate that bortezomib is primarily oxidatively metabolized via cytochrome P450 enzymes, 3A4, 2D6, 2C19, 2C9, and 1A2. The major metabolic pathway is deboronation to form two deboronated metabolites that subsequently undergo hydroxylation to several inactive metabolites.

Preparation and Administration: Bortezomib for injection is supplied as a lyophilized powder for reconstitution. Each sterile single-use vial contains 3.5 mg of bortezomib and 35 mg of mannitol USP. Each vial is reconstituted with 3.5 mL normal (0.9%) saline such that the reconstituted solution contains bortezomib at a concentration of 1 mg/mL. The pH of the reconstituted solution is between 5 and 6. The drug is given without any further dilution as an IV bolus over 3 to 5 seconds. Intact vials of lyophilized bortezomib for injection are stored in a refrigerator at 2° to 8° C (35°-47° F) and protected from light. Stability studies are ongoing to monitor each clinical lot. Product should be administered immediately after reconstitution. The solution as reconstituted is stable for 43 hours at room temperature. Bortezomib is administered as an IV bolus (over 3-5 sec) twice weekly for 2 weeks followed by a 1-week rest period.

Toxic Effects: The most commonly reported adverse events were asthenic conditions (including fatigue, malaise, and weakness; 65%), nausea (64%), diarrhea (51%), decreased appetite (including anorexia; 43%), constipation (43%), thrombocytopenia (43%), peripheral neuropathy (including peripheral sensory neuropathy and peripheral neuropathy aggravated; 37%), pyrexia (36%), vomiting (36%), and anemia (32%). Fourteen percent of patients experienced at least one episode of grade 4 toxicity, with the most common being thrombocytopenia (3%) and neutropenia (3%).

Potential Drug Interactions: No formal drug interaction studies have been conducted with bortezomib. In vitro studies with human liver microsomes indicate that bortezomib is a substrate of cytochrome P450 3A4, 2D6, 2C19, 2C9, and 1A2. Bortezomib may inhibit 2C19 activity (IC_{50} = 18 μM, 6.9 μg/mL) and increase exposure to drugs that are substrates for this enzyme. Patients who are concomitantly receiving bortezomib and drugs that are inhibitors or inducers of cytochrome P450 3A4 should be closely monitored for either toxicities or reduced efficacy. Patients on oral antidiabetic agents receiving bortezomib treatment may experience hypo- or hyperglycemia and require close monitoring of their blood glucose levels and adjustment of the dose of their antidiabetic medication. Finally, patients should be cautioned about the use of concomitant medications that may be associated with peripheral neuropathy (e.g., amiodarone, antivirals, isoniazid, nitrofurantoin, or statins), or with a decrease in blood pressure.

Therapeutic Indications in Hematology: Bortezomib is approved by the Food and Drug Administration for the treatment of multiple myeloma patients who have received at least two prior therapies and have demonstrated disease progression on the last therapy.

CARFILZOMIB

Chemistry and Mechanism of Action: Carfilzomib is an epoxomicin derivate that irreversibly binds to and inhibits the chymotrypsin-like activity of the 20S proteasome. Inhibition of proteasome-mediated proteolysis results in an accumulation of polyubiquinated proteins, which may lead to cell cycle arrest, induction of apoptosis, and inhibition of tumor growth.

Absorption, Fate, and Excretion: Carfilzomib is an investigational product. It has rapid clearance with an elimination half-life of less than 30 minutes and a clearance higher than liver blood flow that suggests there are multiple clearance pathways.

Preparation and Administration: Carfilzomib currently is available investigationally as an intravenous product.

Toxic Effects: Carfilzomib has shown to produce mild to moderate nausea and diarrhea. Respiratory symptoms occur and include cough, dyspnea, and exertional dyspnea. Neurologic symptoms include hypoesthesia, headache, and paresthesia. Additional adverse events seen are fatigue, pyrexia, and peripheral edema.

Drug Interactions: Data not available.

Therapeutic Indications in Hematology: Carfilzomib has been used in multiple myeloma, Hodgkin lymphoma, and non-Hodgkin lymphoma.

IBRUTINIB

Chemistry and Mechanism of Action: Ibrutinib is a first-in-class oral therapy that is a selective, irreversible inhibitor of Bruton tyrosine kinase (BTK) and inhibits BTK activity, preventing B-cell activation and B cell–mediated signaling and inhibiting the growth of malignant B cells that overexpress BTK.

Absorption, Fate, and Excretion: No data available.

Preparation and Administration: Ibrutinib is an investigational agent available as an oral dose.

Toxic Effects: Ibrutinib may cause diarrhea, fatigue, nausea, and skin bruising. Also. transient high lymphocyte count are frequently seen.

Drug Interactions: No data available.

Therapeutic Indications in Hematology: Ibrutinib is used in chronic lymphocytic leukemia/small lymphocytic lymphoma, mantle cell lymphoma, diffuse large B-cell lymphoma, and multiple myeloma.

DASATINIB

Chemistry and Mechanism of Action: Dasatinib is an orally active tyrosine kinase inhibitor against BCR-ABL, SRC family, c-KIT, EPHA2, and PDGFR-β. The primary mechanism of resistance to dasatinib is the T315I mutant clone.

Absorption, Fate, and Excretion: Dasatinib is orally absorbed and extensively metabolized in human liver microsomes, primarily by cytochrome P450 CYP3A4 to an active metabolite. CYP3A4 is the

primary enzyme responsible for the formation of the active metabolite. Flavin-containing monooxygenase 3 and uridine diphosphate-glucuronosyltransferase enzymes are also involved in the formation of dasatinib metabolites. In human liver microsomes, dasatinib was a weak time-dependent inhibitor of CYP3A4. The exposure of the active metabolite, which is equipotent to dasatinib, represents approximately 5% of the dasatinib AUC.

Preparation and Administration: Dasatinab is an oral agent usually taken twice daily without regard to meals.

Toxic Effects: Treatment with dasatinib is associated with severe thrombocytopenia, neutropenia, anemia, and platelet dysfunction. Also seen is fluid retention, including pleural and pericardial effusion, pulmonary edema, severe ascites, and generalized edema. A prolonged QT interval has been observed as well as extensive skin rashes.

Drug Interactions: Dasatinib is a CYP3A4 substrate. Administration with drugs that are CYP3A4 inhibitors may cause increased dasatinib plasma concentrations and subsequent increase in toxicities. Drugs that induce CYP3A4 activity may decrease dasatinib plasma concentrations and decrease its effectiveness. The solubility of dasatinib is pH dependent. Simultaneous administration of SPRYCEL with antacids should be avoided, and there should be 2 hours' separation in the administration of dasatinib and antacids. Long-term suppression of gastric acid secretion by H_2 blockers or proton pump may reduce dasatinib exposure, and antacids are preferred. Dasatinib is a time-dependent inhibitor of CYP3A4; therefore, CYP3A4 substrates may have their plasma concentration altered by dasatinib.

Therapeutic Indications in Hematology: Treatment with dasatinib results in hematologic and cytogenetic responses in patients with lymphoid blast crisis, Philadelphia chromosome-positive (Ph^+), chronic myeloid leukemia, and Ph+ acute lymphoblastic leukemia as initial treatment and in disease-resistant or intolerant to imatinib.

NILOTINIB

Chemistry and Mechanism of Action: Nilotinib is a selective tyrosine kinase inhibitor active against Bcr-Abl kinase Nilotinib binds to and stabilizes the inactive conformation of the kinase domain of ABL protein. Nilotinib is 30-fold more potent than imatinib.

Absorption, Fate, and Excretion: Nilotinib is rapidly absorbed and reaches its peak concentration in 3 hours. Nilotinib AUC was increased by 82% when given 30 minutes after a high-fat meal compared with a fasting state. Its elimination half-life is approximately 17 hours. It is metabolized by oxidation and hydroxylation as well as undergoing metabolism by CYP3A4. None of the nilotinib metabolites have significant pharmacologic activity.

Preparation and Administration: Nilotinib is available in capsules for oral use, containing a 150- or 200-mg nilotinib base, anhydrous (as hydrochloride, monohydrate) with the following inactive ingredients: colloidal silicon dioxide, crospovidone, lactose monohydrate, magnesium stearate, and polyoxamer 188.

Toxic Effects: Nilotinib may cause anemia, neutropenia and thrombocytopenia. Prolonged QT interval and sudden death has occurred. Pruritus, rash, and nausea are common. Also seen with nilotinib are arthralgias and myalgias. Cough has also been associated with nilotinib.

Drug Interactions: Nilotinib is a competitive inhibitor of cytochrome P-450 (CYP) isoenzymes 3A4, 2C8, 2C9, and 2D6 and has the potential to increase concentrations of drugs metabolized by these enzymes. Nilotinib plasma concentration is increased during concomitant use with potent CYP3A4 inhibitors (e.g., atazanavir, clarithromycin, indinavir, itraconazole, ketoconazole, nefazodone, nelfinavir, ritonavir, saquinavir, telithromycin, voriconazole). Decreased nilotinib plasma concentration occurs during concomitant use with potent CYP3A4 inducers (e.g., dexamethasone, carbamazepine, phenobarbital, phenytoin, rifabutin, rifampin, and St. John's wort). Drugs that increase the pH of the upper gastrointestinal tract may decrease the solubility of nilotinib and reduce its bioavailability. The oral administration of esomeprazole resulted in a 34% reduction in the AUC of nilotinib.

Therapeutic Indications in Hematology: Nilotinib has demonstrated activity in the case of chronic myeloid leukemia CML resistance resulted from Bcr-Abl kinase mutations from treatment with imatinib. This includes accelerated phase chronic myeloid leukemia, resistant or intolerant to prior therapy. Acute lymphoid leukemia, Philadelphia chromosome-positive, relapsed/refractory. Blastic phase chronic myeloid leukemia, Resistant or intolerant to imatinib. Chronic phase, Philadelphia chromosome-positive, newly diagnosed. Chronic phase chronic myeloid leukemia, resistant or intolerant to prior therapy.

PLICAMYCIN

Chemistry and Mechanism of Action: Plicamycin, also called mithramycin, forms complexes with DNA and inhibits DNA-directed synthesis of RNA. Plicamycin also inhibits the effect of parathyrin on osteoclasts. The hypocalcemic effect is independent of the antitumor effect.

Absorption, Fate, and Excretion: The pharmacology of plicamycin has been poorly described. Within 15 hours of IV administration, 40% is excreted in the urine. The elimination half-life has been estimated to be approximately 2 hours.

Preparation and Administration: Plicamycin is commercially available as a lyophilized powder in 2.5-mg vials, from which it is reconstituted with 4.9 mL of sterile water for injection. This dose should be further diluted in 1 L of 5% dextrose in water or normal saline and infused over 4 to 6 hours.

Toxic Effects: When plicamycin is used as an antitumor agent, its most common side effects include myelosuppression; elevated liver enzymes; increased serum creatinine and proteinuria; and coagulopathy caused by decreased clotting factors II, V, VII, and X. The drug also causes nausea and vomiting, diarrhea, stomatitis, headache, and irritability. Cutaneous toxicity may occur in up to one-third of patients, manifested by progressive blushing of the face and thickening and coarsening of the skinfolds. The drug can produce severe local irritation if extravasation occurs.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Plicamycin is primarily used to treat hypercalcemia of malignancy. Claims of antitumor activity in the blast phase of CML have been made but have not been confirmed.

BLEOMYCIN

Chemistry and Mechanism of Action: Bleomycin is a glycopeptide. Its antitumor effect correlates with its ability to cause scission of both double- and single-stranded DNA via activated oxygen formed by the iron–bleomycin complex. Bleomycin also affects DNA repair by inhibiting DNA ligase.

Absorption, Fate, and Excretion: Bleomycin is rapidly distributed throughout the body and concentrates in the skin, lung, kidney, peritoneum, and lymph nodes. Its plasma half-life is 2 to 4 hours. Within 24 hours of injection, approximately 50% of an administered dose is excreted unchanged in the urine. Bleomycin elimination

correlates well with creatinine clearance; accordingly, patients with renal failure should receive reduced doses. In the tissues, bleomycin is inactivated by bleomycin hydrolase. Tissues lacking this enzyme, such as the lungs and skin, are more susceptible to the drug's toxic effects.

Preparation and Administration: Bleomycin is commercially available in vials containing 15 U (approximately equivalent to 15 mg), from which it is reconstituted for injection with 3 to 5 mL of sterile water, normal saline, 5% dextrose in water, or bacteriostatic water. For IV infusion, the reconstituted solution can be further diluted with either normal saline or 5% dextrose in water and administered over 5 minutes. Bleomycin can also be administered by the subcutaneous, intravenous, intramuscular, intracavitary, and intraarterial routes. Because patients with lymphomas are at an increased risk of anaphylactoid reactions, which may not occur until 12 hours after administration, the first two doses should be intramuscular "test doses" of 1 to 2 mg. If no reactions occur, full doses may be given.

Toxic Effects: The most serious toxic effect is interstitial pneumonitis, which is dose related and occurs in approximately 10% of patients treated with cumulative doses of greater than 350 to 400 U. The interstitial pneumonitis may evolve into life-threatening pulmonary fibrosis. Pulmonary toxicity is more common in patients older than 70 years, in those receiving a total dose of greater than 400 U, and in those who received prior radiotherapy to the lung. It is important to emphasize, however, that the pulmonary toxicity is unpredictable; it has been reported in patients who had none of these risk factors and has occurred in a patient after administration of only 20 U. Some reports suggest that an increased concentration of inspired oxygen acts synergistically with bleomycin to produce pulmonary fibrosis. During critical illness and perioperatively, therefore, an attempt should be made to maintain the inspired oxygen concentration at 21%. The early phases of the pulmonary toxicity are clinically manifested by dyspnea and fine rales. Although corticosteroids are often used in this setting, it is not clear that they are of benefit.

Mucocutaneous toxicity occurs in 50% of patients treated and is manifested by hyperpigmentation, pruritic erythema, mucositis, desquamation of the plantar surface skin of the hands or feet, ridging of the nails, and alopecia. The mucositis can be severe and is the acute dose-limiting toxic effect. Febrile reactions, which occur a few hours after bleomycin administration and may last 4 to 12 hours, are also common. Fever becomes less frequent with continued use of the drug and can usually be prevented by concurrent administration of glucocorticosteroids (e.g., 100 mg of hydrocortisone). Bleomycin has virtually no myelosuppressive effect. Anaphylactoid reactions are observed in approximately 1% (up to 8% in some series) of patients with lymphomas treated with bleomycin.

Potential Drug Interaction: Bleomycin, administered with other drugs for the treatment of lymphorrhea, can decrease the oral bioavailability of digoxin and the pharmacologic effect of phenytoin and certain anesthetic drugs.

Therapeutic Indications in Hematology: Bleomycin is often incorporated in the chemotherapy regimens of Hodgkin disease (ABVD and MOPP-ABV hybrid regimens) and non-Hodgkin lymphoma (MACOP-B, PROMACE-CYTABOM, M-BACOD, and CHOP-Bleo).

ASPARAGINASE

Chemistry and Mechanism of Action: Asparaginase contains the high-molecular-weight enzyme L-asparaginase amidohydrolase, type EC-2, derived from *Escherichia coli*. Asparaginase hydrolyzes serum asparagine to nonfunctional aspartic acid and ammonia, depriving tumor cells of a required amino acid; thus tumor cell proliferation is blocked by the interruption of asparagine-dependent protein synthesis. The drug appears to be most active in the G_1 phase.

Absorption, Fate, and Excretion: Asparaginase is not absorbed orally. Its plasma half-life varies from 8 to 30 hours and is not influenced by dosage, age, sex, surface area, or renal or hepatic function.

Preparation and Administration: Asparaginase is commercially available in vials containing 10,000 IU of asparaginase in 80 mg of mannitol. For IV use, the drug should be reconstituted with 5 mL of either sterile water or sodium chloride for injection and injected in the tubing of a freely running infusion of either normal saline or 5% dextrose in water over 30 minutes. For intramuscular or subcutaneous use, each vial should be reconstituted with 2 mL of sodium chloride for injection to obtain a 5000-U/mL solution. For dosages that exceed 2 mL, use of two injection sites is recommended. For both IV and intramuscular administration, the drug must be used within 8 hours of reconstitution, and only if it is clear. Because of the possibility of hypersensitivity reactions (particularly in patients with lymphomas), an intradermal skin test is recommended before initial administration of asparaginase or when 1 week has elapsed between doses. For this test, 2 IU should be injected intradermally and observed for a wheal or erythema for 1 hour. A negative skin test result, however, does not preclude possible development of a hypersensitivity reaction. It is recommended that oxygen, epinephrine, and corticosteroids be available at the bedside during administration of the drug. For allergic patients, the *E. coli* form of asparaginase should be replaced by the asparaginase derived from *Erwinia carotovora,* provided by the National Cancer Institute as an investigational group C agent.

Toxic Effects: The toxicity of asparaginase is reported to be greater in adults than in children. Anorexia, nausea, or vomiting occurs in approximately one-third of patients. Most of the other side effects can be divided into two main groups, those related to hypersensitivity reactions to the foreign protein and those resulting from decreased protein synthesis. The hypersensitivity reaction is characterized by urticaria, laryngeal edema, bronchospasm, or hypotension and may occur with the initial dose of the drug even if the skin test result is negative. More commonly, however, allergic phenomena are observed after multiple courses of treatment. Adverse effects related to the inhibition of protein synthesis include hypoalbuminemia and decreases in serum fibrinogen, prothrombin, antithrombin III, and other coagulation factors, which may lead to both clotting and hemorrhagic complications; decreased serum insulin with hyperglycemia; and decreased serum lipoproteins. In 25% or fewer of patients, cerebral dysfunction, characterized by confusion, stupor, and frank coma, can occur. Although the neurotoxic effects resemble those of ammonia toxicity, they are apparently caused by low concentrations of either L-asparagine or L-glutamine in the brain. Acute pancreatitis, which may progress to severe hemorrhagic pancreatitis, may occur in 15% of patients. Elevation of liver enzymes and serum bilirubin is almost universal and is histologically represented by fatty metamorphosis. Liver toxicity, although usually not clinically significant, has resulted in occasional fatalities. Asparaginase can occasionally produce renal functional impairment with oliguric renal failure.

Potential Drug Interactions: When asparaginase is administered immediately before or concurrent with methotrexate, it decreases the cytotoxic effect of the latter. When administered to patients with acute leukemia 9 to 10 days before or shortly after methotrexate, however, asparaginase appears to enhance the cytotoxic effect of methotrexate. Concurrent administration of asparaginase with vincristine may increase vincristine's neurotoxic effects, but this effect appears to be less pronounced when asparaginase is given after vincristine. The effects of asparaginase on liver function may potentially interfere with the activation or metabolism of other cytotoxic agents.

Therapeutic Indications in Hematology: Asparaginase is used in combination therapy for remission induction of acute lymphocytic leukemia.

GLUCOCORTICOIDS

Chemistry and Mechanism of Action: Glucocorticoids are synthetic compounds derived from the natural adrenal hormone cortisol. Glucocorticoids mediate their biologic actions predominantly by binding to their cytosolic receptor, which then translocates to the nucleus. There, as a homodimer, it binds to specific DNA sequences located in the regulatory regions of a number of genes. Gene transcription can be upregulated or downregulated by glucocorticoids. They can also inhibit binding of the AP-1 transcription factor to its DNA consensus sequence site. Lymphocytes treated with glucocorticoids undergo apoptosis mediated by glucocorticoid receptors. An early cytostatic phase is marked by growth inhibition and cessation of proliferation caused by inhibition of cellular uptake of glucose, amino acids, and nucleosides as well as inhibition of macromolecular synthesis. This is followed by a cytolytic phase characterized by chromatin condensation and internucleosomal DNA cleavage.

Absorption, Fate, and Excretion: Many synthetic glucocorticoids are available, the three most commonly used in hematology being prednisone, dexamethasone, and methylprednisolone. The glucocorticoids are well absorbed orally and are primarily metabolized in the liver. Unlike the other two glucocorticoids, the activity of prednisone depends on hepatic conversion to the 11-hydroxy form (prednisolone). Whereas the biologic half-lives of prednisone and methylprednisolone are approximately 12 to 36 hours, dexamethasone has a biologic half-life of 36 to 72 hours. Plasma half-lives for all three drugs are within the range of 3 to 4 hours. Compared with cortisol, the relative antiinflammatory potencies of dexamethasone, methylprednisolone, and prednisone are 25, 5, and 4, respectively, for equivalent doses.

Preparation and Administration: Prednisone is available only for oral administration, but methylprednisolone and dexamethasone are available in oral and parenteral dosage forms.

Toxic Effects: When glucocorticoids are used for less than 14 days, as is often done when they are used in combination with other cytotoxic agents, the most common side effects include euphoria, insomnia, psychosis, hyperglycemia, hypokalemia, increased appetite, metabolic alkalosis, proximal muscular weakness, and fluid retention with edema formation and hypertension. When used on a chronic basis, glucocorticoids also may induce a "Cushingoid" appearance, easy bruisability, peptic ulcers, osteoporosis, subcapsular cataracts, and an increased susceptibility to infections related to impaired cellular immunity. Because of this, H_2 blockers, antifungal agents (e.g., ketoconazole), and sulfamethoxazole–trimethoprim have been used in certain glucocorticoid chemotherapy combinations.

Potential Drug Interactions: Glucocorticoids interact with a variety of drugs, including barbiturates, oral contraceptives, erythromycin, hydantoins, rifampin, isoniazid, and salicylates. Given the wide range of doses of glucocorticoids used, however, these interactions are of no major clinical relevance.

Clinical Indications in Hematology: Glucocorticoids have direct anticancer activity in many hematologic malignancies, including acute lymphoblastic leukemia, chronic lymphocytic leukemia, Hodgkin disease, non-Hodgkin lymphoma, and plasma cell neoplasms. Because of their efficacy and toxic profiles, which do not overlap with the toxic effects of the other cytotoxic agents, glucocorticoids are used in many chemotherapy regimens. In addition, they are useful in the management of hypercalcemia secondary to myeloma and lymphomas and are of paramount importance in the treatment of autoimmune hematologic disorders.

BRYOSTATIN

Chemistry and Mechanism of Action: Bryostatin is a macrocyclic lactone that activates protein kinase C by causing translocation of the enzyme from the cytoplasmic to the membrane-associated active fraction during short-term exposure and protein kinase C membrane depletion and inactivation at long-term exposure.

Absorption, Fate, and Excretion: There is no reliable assay for determining the fate of bryostatin in humans.

Preparation and Administration: Bryostatin is supplied and prepared as a two-part formulation. Vial one contains 0.1 mg of lyophilized bryostatin as a white powder and is combined with 1 mL of a PET diluent (60% polyethylene glycol 400, 30% dehydrated ethyl alcohol, and 10% polysorbate 80). This solution must be further diluted with 9 mL of 0.9% sodium chloride injection and yields a 10-μg/mL solution of bryostatin. Polyvinyl chloride (PVC) bags should not be used because there may be leaching of a plasticizer and some limited adsorption. The drug may be further diluted with 0.9% sodium chloride or dextrose 5% in water to a concentration of 0.15 μg/mL to 0.75 μg/mL in a glass or polyolefin container. Non-PVC tubing is recommended.

Toxic Effects: Dose-limiting myalgias, eye pain, and photophobia are frequently seen. Phlebitis is common with peripheral administration. Fatigue, headache, nausea and vomiting, and diarrhea are also seen. Thrombocytopenia, neutropenia, and anemia occur, although infrequently.

Drug Interactions: No known reports.

Therapeutic Indications in Hematology: Bryostatin has activity against myeloid leukemia, chronic lymphocytic leukemia, non-Hodgkin lymphoma, and multiple myeloma. Enhanced tumor effect has occurred with the combination of bryostatin with vincristine, cisplatin, and cytarabine.

FLAVOPIRIDOL

Chemistry and Mechanism of Action: Flavopiridol is a semisynthetic flavone and selective inhibitor of CDKs 1, 2, 4-7, PKC, PKA, and platelet-derived growth factor causing cell cycle arrest. It also may inhibit CDK9/TEFb, which causes downregulation of McI-1, BIRC4, cyclin D1, and p21CIP1.

Absorption, Fate, and Excretion: Flavopiridol is 94% protein bound and is metabolized by the UDP glucuronyltransferase isoenzymes. Its half-life varies with infusion duration and ranges from 3.5 hours (1-hour infusion) to 27 hours (72-hour infusion).

Preparation and Administration: Flavopiridol is supplied as a 10 mg/mL yellow-greenish solution in a 5-mL vial. Contents may be diluted in either 5% dextrose injection or 0.9% sodium chloride injection to achieve a final concentration of 0.09 to 1 mg/mL. If the drug is administered through peripheral IV access, a concentration of less than 0.5 mg/mL is thought to decrease thrombotic complications. Flavopiridol has been administered as a 1-, 24-, and 72-hour infusion.

Toxic Effects: Grade 4 neutropenia and grade 3 lymphocytopenia occur and are more common with shorter durations of infusion. Thrombocytopenia is seen infrequently. Secretory diarrhea is a dose-limiting toxicity and may last for up to 3 days. Orthostatic hypotension is a frequently seen occurrence. Thrombosis with the 72-hour infusion duration was far more common than in the shorter infusion durations. A fatigue rate approaching 75% has been reported. Other toxicities include pleuritic chest pain, hyperbilirubinemia, and nausea.

Potential Drug Interactions: Paclitaxel in combination with flavopiridol has been associated with severe dose-limiting neutropenia.

Therapeutic Indications in Hematology: Flavopiridol's place in therapy is still being assessed. It has activity and use in hematologic malignancies, including mantle cell lymphoma, leukemias, and multiple myeloma. It may cause potential solid tumors in combination with other agents.

TANESPIMYCIN (17-AAG, GELDANAMYCIN, NSC 330507)

Chemistry: Tanespimycin is a water-soluble benzoquinone ansamycin antibiotic that binds to heat shock protein 90.

Fate, Absorption, and Excretion: Tanespimycin has a mean terminal half-life of 2.3 hours and is primarily metabolized by liver microsomal enzymes, specifically CYP3A4. One metabolite, 17-AG, is known to be active and has a mean terminal half-life of 4.6 hours. Peak plasma concentrations of 17-AAG and 17-AG occur at 30 and 60 minutes, respectively. 10.6% of 17-AAG and 7.8% of 17-AG is recovered in the urine over a 72-hour period.

Preparation and Administration: Tanespimycin is available as a single use amber vial containing 50 mg of tanespimycin in 2 mL of dimethylsulfoxide. Before administration, the tanespimycin concentrate must be completely thawed at room temperature (over ≤1 hour). Incomplete thawing affects the concentration of the drug because of changes in volume. Tanespimycin concentrate must be diluted to 1 mg/mL by withdrawing 2 mL and adding it to 48 mL of EPL diluent 2% egg phospholipids with 5% dextrose in water. A clear solution should be obtained with gentle mixing. Shaking should be avoided to prevent foaming. No further dilution is required and the final solution should be dispensed in a glass bottle. A 0.45 micron filter may be used, but is not required. The infusion should be completed within 8 hours of mixing. Intact vials of Tanespimycin should be stored in the freezer (−10° to −20°C). EPL diluent should be stored in the refrigerator (2°-8°C) and not frozen. Administration is by IV infusion.

Toxicity: Anemia, diarrhea, nausea, vomiting, fatigue, transaminitis, and muscle pain.

Drug Interactions: Tanespimycin is metabolized by CYP3A4. Agents that alter CYP3A4 activity may affect drug levels and metabolism, although this has not been shown to affect clinical use.

Therapeutic Uses: Lymphoma and leukemia in clinical trials.

IMATINIB (GLEEVEC)

Chemistry and Mechanism of Action: Imatinib, a phenylaminopyrinadine derivative, is a selective protein tyrosine kinase inhibitor effecting BCR-ABL tyrosine kinase. This enzyme is found commonly in chronic myeloid leukemia and in some clones of acute lymphoblastic leukemia. Imatinib also inhibits the kinases for platelet-derived growth factor, stem cell factor, and KIT.

Absorption, Fate, and Excretion: Imatinib is well absorbed and achieves peak levels within 2 to 4 hours and follows linear pharmacokinetics at the standard doses. The cytochrome P450 is the major route of metabolism with CYP3A4 being the primary pathway. An *N*-desmethyl piperazine is the main metabolite and is active. Pediatric patients follow the same pharmacokinetics as in adults.

Preparation and Administration: Imatinib is available in a film-coated tablet. In its pure form, it is a white to brownish to yellowish powder and is soluble in aqueous buffers of less than 5.5.

Toxic Effects: Gastrointestinal effects are common and include nausea and diarrhea. Muscle cramps are seen in one-third of patients receiving imatinib. Myelosuppression reflected as thrombocytopenia, anemia, and neutropenia occurs, with thrombocytopenia and neutropenia seen more frequently in patients in accelerated phase or blast crisis. Fluid retention is dose related and is exhibited as edema and weight gain, but pleural and pericardiac effusions are also seen. Fatigue and headache, although low grade, occur in 25% of patients.

Potential Drug Interactions: Drugs that inhibit CYP3A4 may increase imatinib plasma concentrations; these include ketoconazole, itraconazole, erythromycin, and clarithromycin. CY3A4 inducers that may decrease plasma concentration of CY3A4 are dexamethasone, rifampin, phenytoin, and carbamazepine. Imatinib increases concentrations of simvastatin, cyclosporine, and warfarin, along with other medications that are metabolized by CYP3A4.

Therapeutic Indications in Hematology: Imatinib is considered first-line therapy in Philadelphia-positive CML and has activity in accelerated or blast-phase CML. Some effect has been shown in ALL as well as hypereosinophilic syndrome and polycythemia vera.

TOPOTECAN (HYCAMTIN)

Chemistry and Mechanism of Action: Topotecan is a semisynthetic derivative of camptothecin that stabilizes a complex between DNA topoisomerase I and DNA. The cytotoxic effect of this drug is believed to result from the collision of DNA replication forks with a ternary complex of topoisomerase I, DNA, and topotecan. The resulting double-strand DNA breaks are lethal. The lactone form of topotecan, which predominates at an acidic pH, is a much more potent inhibitor of DNA topoisomerase I.

Absorption, Fate, and Excretion: At neutral or physiologic pH, the carboxylate form of topotecan is favored, and at a pH less than 7, the lactone form is favored. Topotecan has been given as a bolus or by continuous infusion. In less than 1 hour after infusion, most of the circulating drug in the plasma is in the carboxylate form because of the physiologic pH. The terminal half-life of the lactone form of this S phase–specific agent is 2.6 hours, and the terminal half-life of the total drug is 3.3 hours. Thirty-six percent of an IV dose is excreted unchanged in the urine, and there is a 1.5-fold concentration of the drug in bile. Cerebrospinal fluid levels of topotecan lactone reach approximately 32% of plasma levels. Dose adjustment is required for a creatinine clearance less than 60 mL/min, but no adjustment is necessary for a bilirubin up to 10 mg/dL.

Preparation and Administration: Topotecan is commercially available as 4-mg vials that are reconstituted with 4 mL of sterile water. This solution can be further diluted in normal saline or 5% dextrose in water and should be used immediately.

Toxic Effects: The dose-limiting toxicity for topotecan for all schedules is neutropenia. Thrombocytopenia and anemia are less common, although there is an increase in thrombocytopenia with continuous infusion schedules. Other less common and mild toxicities include nausea, vomiting, diarrhea, fever, fatigue, alopecia, skin rash, and increased liver function test results. Mucositis has been seen with prolonged infusion schedules over 5 days or when topotecan is given in higher doses.

Potential Drug Interactions: In vitro data suggest that there may be some synergism if a topoisomerase I inhibitor is given before a topoisomerase II inhibitor. In vitro data also suggest that synergism may be seen if a topoisomerase I inhibitor (topotecan) is given after an alkylating agent, suggesting that topoisomerase I may be involved in the repair of alkylator-induced DNA damage.

Therapeutic Indications in Hematology: Topotecan has activity in myelodysplastic syndromes, acute myeloid leukemia, chronic myeloid leukemia, and multiple myeloma.

VORINOSTAT (ZOLINZA)

Chemistry and Mechanism of Action: Vorinostat is a histone deacetylase (HDAC) inhibitor. It inhibits HDAC 1, HDAC2, HDAC3, and HDAC6 at nanomolar concentrations. Inhibition prevents removal of the acetyl groups from lysine residues in target histones and transcription factors. Loss of deacetylase function results in persistence of acetyl groups on histones, resulting in larger segments of open chromatin and a general increase in gene expression. Often this promotes differentiation and cell cycle arrest with apoptosis. The number of genes affected continues to grow so that the impact of vorinostat is complex.

Absorption, Fate, and Excretion: Reported pharmacokinetics after a 400-mg oral administration are an AUC of 5.5 micromolar-hours, a C_{max} of 1.2 micromolar, and T_{max} of 2 to 10 hours. Fatty meals decrease the rate of absorption but increase overall drug levels. There is no recommended dosing relative to meals. Vorinostat is heavily plasma protein absorbed. It undergoes glucuronidation hydrolysis, and later β-oxidation to inactive metabolites. Little is excreted unchanged.

Preparation and Administration: Oral dosing of 400 mg with food is standard. If side effects are noted, reduce the dose to 300 mg. There is no approved pediatric dosing.

Toxic Effects: Many side effects are noted. Common are fatigue, thrombocytopenia, muscle spasms, and anorexia. Serious reported adverse effects in clinical trials included pulmonary embolism in 4.7% and anemia in 2.3%.

Potential Drug Interactions: Vorinnostat can prolong Coumadin effect, raising the international normalized ratio. It can also induce glucose intolerance.

Therapeutic Indications in Hematology: Vorinostat is approved for cutaneous manifestations of cutaneous T-cell lymphoma in patients who have become refractory to standard treatments. It is being tested in other disorders such as myeloma and leukemias to determine whether it works through the HDACs or through altered expression of numerous proteins.

CHAPTER 56

RADIATION THERAPY IN THE TREATMENT OF HEMATOLOGIC MALIGNANCIES

Andrea K. Ng and Peter M. Mauch

In 1895, x-rays were first described by the German physicist Wilhelm Conrad Röntgen. Shortly after, in 1898, Antoine Henri Becquerel discovered radioactivity, and in the same year, the Curies isolated radium. The therapeutic potential of x-rays was first demonstrated in 1897, when the German surgeon Wilhelm Alexander Freund reported the disappearance of a hairy mole after x-ray treatments. In the early part of the century, radiation therapy consisted of primitive equipment, crude dosimetry, and little knowledge of normal tissue or tumor radiation biology. Although initial tumor shrinkage was achieved, the superficial characteristics of the radiation therapy deposited high doses in the skin and subcutaneous tissues, causing burns and ulceration, and underdosed deeper tumors, resulting in suboptimal long-term control. By 1930, the development of reliable orthovoltage machines enabled treatment of deeper tumors. The concept of fractionated radiation therapy was also developed in the 1930s. However, even with the more penetrating beams, adequate treatment of tumors deep in the abdomen or chest frequently was associated with complications involving the skin, muscles, heart, or bowel. Modern high-energy megavoltage equipment became available in the 1950s with cobalt 60 (^{60}Co). The linear accelerator, designed from microwave technology developed for radar during World War II, was first used in the United States by Kaplan and his group at Stanford University in the late 1950s.

Many of the principles and early techniques of radiation therapy for hematologic malignancies came from pioneering work in Hodgkin lymphoma. Vera Peters, in 1950, was the first physician to present definitive evidence that radiation therapy was a curative modality for patients with early-stage Hodgkin lymphoma. She did this by treating patients with limited-stage disease who were cured with high-dose, fractionated radiation therapy. Patients received 1800 to 5000 R to areas of involvement, with the highest dose given to patients with early-stage disease. She reported 5-year and 10-year survival rates of 88% and 79%, respectively, for patients with stage I Hodgkin lymphoma, rates that were incredibly high for a disease at that time in which virtually no one survived 10 years. The early success of radiation therapy in the treatment of lymphoma and Hodgkin lymphoma provided encouragement for the treatment of other tumors. These developments in radiation therapy are detailed in the next sections.

TYPES OF RADIATION

Electromagnetic Radiation

The ionizing radiation (photons) used during clinical treatment strategies is part of the electromagnetic spectrum. The energy of x-rays, described in terms of electron volts (eV), eject an electron from the target tissue, thus the term *ionizing radiation.* High-energy radiation is produced by linear accelerators by radioactive decay. The photons produced from radioactive decay are called gamma rays; they are identical to the x-rays produced by linear accelerators. Radioactive isotopes can be produced that emit gamma rays at sufficient energy and the dose to be used in clinical external-beam therapy. The most common isotope for external-beam irradiation is ^{60}Co (half-life 5.26 years). This isotope was in use before the availability of linear accelerators. The decay of ^{60}Co to nickel produces two gamma rays of energy that are 1.17 and 1.33 MeV. Linear accelerators generate photon beams by bombarding a target with electrons. Higher energy and thus more penetrating x-rays can be produced. Furthermore, linear accelerators have a smaller source and as a result can produce a much sharper beam edge compared with a cobalt machine.

Particle Radiation

High-energy electrons are one of the most frequently used forms of particle radiation in cancer treatment. They can be produced directly from a linear accelerator with the proper extraction technique. The typical energy range for electrons is 6 to 20 MeV, which allows treatment of superficial tumors up to a depth of 5 cm, with a characteristic sharp drop-off in dose beyond the prescribed depth.

Neutrons, protons, helium, carbon ions, and pi-mesons are other particles used for experimental radiation therapy. Because of their mass and charge, these particles can be sharply localized in tissue (Bragg peak), allowing precise localization, and potential sparing of normal tissues. In recent years, comparative dosimetry studies have been reported using proton beam therapy for treating mediastinal lymphoma, although uncertainty in radiologic path lengths of the proton beam may result in the only benefit in selected cases depending on the disease location.

RADIATION TREATMENT PLANNING AND DELIVERY

Radiation treatment requires a precise knowledge of normal anatomy and a detailed knowledge of growth patterns of tumors. Patient treatment plans are developed using a simulator before commencement of radiation therapy. Historically, in the two-dimensional (2D) planning era, fluoroscopy, bony landmarks, or other anatomic structures visible fluoroscopically were typically used to guide treatment field design. Three-dimensional conformal radiation therapy (3D CRT), which provides a 3D model of the patient's anatomy and tumor, allows more accurate tumor targeting while sparing neighboring critical normal organs. Beam's eye view display is used to select optimal beam directions and design beam apertures. Intensity-modulated radiation therapy (IMRT), an advanced form of 3D CRT, is increasingly incorporated into treatment of selected cases of lymphoma.[1-5] It is based on the use of optimized nonuniform radiation beam intensities incident on the patient, allowing dose "sculpting" and dose "painting," and has the potential to further improve the therapeutic ratio and reduce radiation toxicity. IMRT may especially benefit treatment to head and neck sites eliminate and where treatment is required.

Positron emission tomography (PET) scanning using ^{18}F-fluorodeoxyglucose is currently used in the staging, restaging, and follow-up of most lymphoma patients. In addition, for radiation treatment planning, the accuracy of tumor targeting can be improved by incorporating information from the PET scan into the planning process. The fusion of prechemotherapy PET data with computed tomography (CT) simulation information has been shown to lead to significant modifications of the treatment strategy and the

radiotherapy planning in lymphoma patients (Table 56-1). As radiation treatment fields evolve toward involved-node radiation therapy (discussed later), where accurate delineation of prechemotherapy tumor volume is critical, PET-CT fusion planning will likely be increasingly used.

RADIATION BIOLOGY

Four R's of Radiation Biology

The laboratory and clinical findings of classic radiation biology have been defined in terms of the four R's of repair, redistribution, repopulation, and reoxygenation.

Repair

Two basic types of repair have been defined operationally: sublethal damage repair and potentially lethal damage repair. A radiation cell survival curve is characterized by a shoulder region and a terminal exponential portion (Fig. 56-1). In the shoulder region, a minimum number of targets must be hit before cell death occurs. This is defined as sublethal injury. Sublethal damage repair refers to the repair that occurs within the shoulder region, with the reappearance of another shoulder during that time. Potentially lethal damage repair refers to the increase in survival over time after a single treatment. If the cells remain in situ for a number of hours posttreatment, the proportion of surviving cells will increase. It is likely that similar biochemical mechanisms are involved to some extent for both, although the importance to clinical outcome of each of these repair processes is not completely understood.

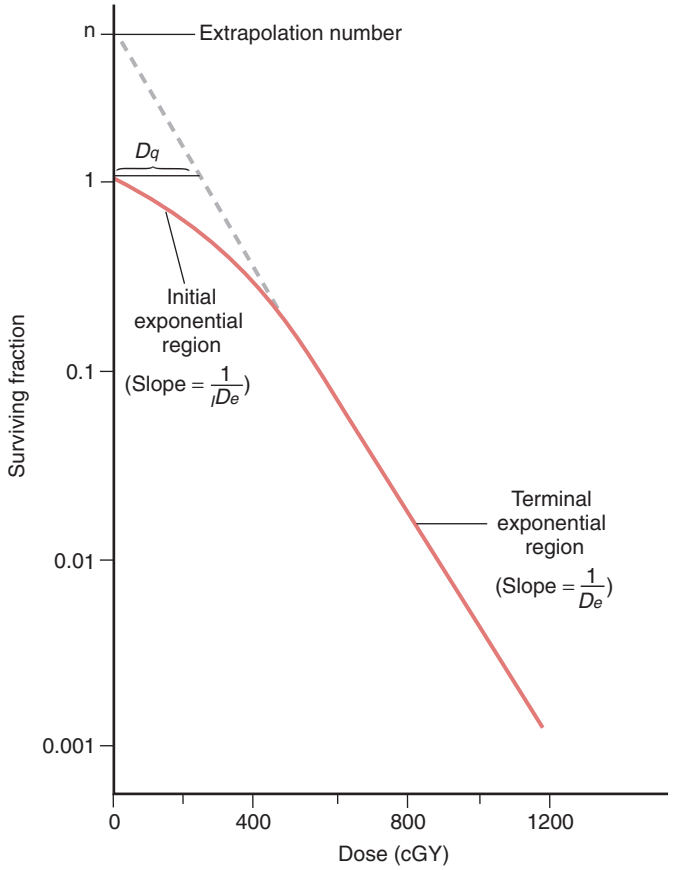

Figure 56-1 CELL SURVIVAL CURVE. D_o, Dose required to reduce the fraction of surviving cells by 37%; D_q, quasi-threshold dose. *(Modified from Withers HR: Biologic basis of radiation therapy. In Perez CA, Brady LW, editors:* Principles and practice of radiation oncology, *ed 2, Philadelphia, 1992, JB Lippincott, p 72.)*

Redistribution

Redistribution refers to the synchronization of the cell cycle that occurs after a single dose of radiation. Cells have decreasing radiosensitivity as from M/G2 to G1, to early S to late S phase. The relative radioresistance of S phase has prompted the combined use of radiation with S phase–specific drugs. An example is the delivery of radiation therapy concurrently with cycle active agents such as 5-fluorouracil (5-FU) in gastrointestinal malignancies.

Repopulation

Tumors and normal tissues repopulate during a course of irradiation. Normal tissue repopulation is observable with the healing of mucosal and skin reactions that takes place despite continuing radiation. The repopulation of tumors has been inferred from split-course radiation regimens in which there are a few weeks of no treatment between treatment segments. In settings in which the total dose is the same, local control is worse for split-course than for continuous treatment.

Reoxygenation

Hypoxic cells are relatively radioresistant. For the same portion of cell killing, hypoxic cells require two to three times the dose as the same cells treated in normoxic conditions. It would be expected that the proportion of hypoxic cells would increase rapidly after a few treatments as the more sensitive oxygenated cells are killed. In general, however, this is not the case. A process called reoxygenation takes place that maintains the proportion of hypoxic cells at a relatively constant number. The exact mechanism of reoxygenation is not known, but likely involves shifts in blood flow. Without reoxygenation, radiation therapy probably would not cure many solid tumors.

Fractionation and Dose

The standard fractionation scheme for radiation therapy is 180 to 200 cGy/day, 5 days per week. The total dose depends on the clinical setting and type of tumor. For Hodgkin lymphoma, after a complete response to chemotherapy, doses of 2000 to 3000 cGy are adequate depending on the presence or absence of risk factors. The approximate dose needed to achieve a probability of more than 95% local control of an indolent non-Hodgkin lymphoma is 3000 to 3600 cGy. In the setting of combined modality therapy, doses of 3000 to 4000 cGy are typically used for aggressive lymphomas, but higher doses of 4500 to 5000 cGy may be needed for chemotherapy-resistant diseases. Hypofractionation (high dose per fraction) is useful for palliative regimens. Relatively large doses are given one to four times per week, resulting in a large total weekly dose, such as 3000 cGy in 10 fractions over 2 weeks. Accelerated fractionation refers to keeping the same total dose, but decreasing the time over which it is given. Such a regimen might be used for a rapidly growing tumor, such as Burkitt lymphoma or refractory lymphoma. Hyperfractionation uses a small single dose given two to three times per day such that the total time is about the same as with standard fractionation, but the total dose must be higher to obtain the same effect. The lower dose per fraction spares late-responding tissues relative to tumor. Accelerated hyperfractionation is a hybrid regimen of delivering small doses two to three times per day over a shortened time period. In considering the total dose received by a patient, it is imperative to consider the dose per fraction, the number of doses per week, the total dose, the total treatment time, and when considering retreatment, the time elapsed since completion of the previous course of therapy.

Clinical Radiation Tolerance

The extent and frequency of injury to normal tissues depend on both radiation dose and volume treated. The risk can be enhanced by surgery and chemotherapy. Specific organ tolerance is not known, but estimates can be derived from reports of small numbers of patients.

Central Nervous System

Brain tolerance is about 5500 to 6000 cGy in small fractions, but small volumes can tolerate higher doses. Radiation myelitis can occur at doses in excess of 5000 cGy. The combined use of certain cytotoxic agents may increase the risk for spinal cord injury. The peripheral nervous system has a higher tolerance, and injury is uncommon unless fields overlap.

Heart

Radiation injury to the heart may involve a number of different cardiac tissues. Cardiac injury is rare unless the entire heart is treated with more than 3000 cGy. Anthracycline therapy enhances the risk for myocardial injury, and the total cardiac dose is limited to 1500 cGy in patients who have received anthracycline-containing chemotherapeutic regimens.

Lung

Fractionated doses as low as 2000 cGy or single doses as low as 800 cGy can cause radiation pneumonitis. Acute radiation pneumonitis can occur up to 6 months after treatment and is characterized by a dry cough, dyspnea and low-grade fever, and radiographic changes within the radiation fields. Long-term fibrosis and loss of pulmonary function depends on the presence of underlying lung pathologic conditions and the use of chemotherapeutic agents, in particular bleomycin, which may lower the threshold for clinical radiation lung injury. Using 3D radiation planning, dose-volume histograms of the lungs can be generated. In a typical mantle field, 25% to 30% of lungs may receive up to 2000 cGy, but most patients remain asymptomatic in this dose range.

Kidney

A portion of the kidney that receives a total dose in excess of 2000 cGy will permanently lose function. The development of late hypertension or renal failure depends on the volume of kidney irradiated. Even if a portion of one kidney is treated to a high dose, it is rare to see any clinical signs or symptoms. If cisplatin is administered after kidney irradiation, the toxicity of the platinum may be increased.

Liver

The irradiation of a large segment of liver to a dose in excess of 3000 cGy produces a clinical syndrome of hepatomegaly, ascites, and elevated liver function test results. Radiation injury is similar to that of venoocclusive disease, a syndrome that occurs with high-dose alkylating agent therapy used in some marrow transplantation conditioning regimens. If not fatal, radiation liver injury completely resolves.

Gastrointestinal Tract

The gastrointestinal tract is modestly sensitive to irradiation, with small bowel tolerance lower than that of the esophagus or large bowel. During radiation therapy, patients who receive large abdominal or pelvic fields get some degree of bowel irritation. Permanent gastrointestinal injury occur at doses above 4500 cGy and may require surgical excision of the damaged bowel segment, but this should be done only after a trial of conservative management.

Other Organs

Virtually all organs are susceptible to injury. The following are the lower limits for a permanent injury for some other organs: bone marrow stroma, 4000 cGy; spleen with functional asplenia, 4000 cGy; ovary, 2000 cGy; skin, 5500 cGy; salivary and endocrine glands, 4500 cGy; bladder, 6000 cGy; peripheral nerve, bone, and muscle, 6000 cGy; oral cavity mucosa, 6000 cGy. Acute reactions (e.g., bowel, skin, mucous, hair loss, blood count depression) occur 2 to 3 weeks after the start of treatment. These systems may recover despite an early decrease in function and the continuation of therapy. Conservative management helps a patient get through treatment with a minimum interruption of treatment. As a rule, the presence or extent of an acute reaction does not predict the likelihood of a delayed reaction. A major concern after treatment with radiation or chemotherapy is the development of secondary malignancies. The risk is especially well documented in long-term survivors of Hodgkin lymphoma and has been

shown to be directly related to radiation dose and size of the treatment field. The trend toward reducing radiation dose and field size in the treatment of Hodgkin lymphoma will hopefully reduce the future risk for radiation-related second malignancies.

SPECIFIC USES OF RADIATION THERAPY FOR TREATMENT OF HEMATOLOGIC AND LYMPHOID MALIGNANCY

Early-Stage Hodgkin Lymphoma

The current standard therapy for stage I-II Hodgkin lymphoma is doxorubicin (Adriamycin), bleomycin, vinblastine, and dacarbazine (ABVD) chemotherapy followed by involved-field radiation therapy, yielding 5-year freedom-from-treatment-failure rates of approximately 95% and 85% in patients with favorable-prognosis and unfavorable-prognosis early-stage disease, respectively.[6,7] For patients with early-stage disease without any risk factors according to the German Hodgkin Study Group (GHSG) criteria (lack of large mediastinal adenopathy, extranodal disease, elevated sedimentation rate/B symptoms and three or more sites of disease), the GHSG HD10 trial showed that reduced treatment with only two cycles of ABVD followed by involved-field radiation therapy to 20 Gy is adequate in these patients.[6] In patients with risk factors, however, after four cycles of ABVD, results of the GHSG HD11 trial showed that a dose of 30 Gy is needed.[6]

In addition to a reduction of radiation dose, there is also increasing interest in further reducing radiation field size, from involved-field to involved-node radiation therapy, based on the known patterns of disease relapse after chemotherapy. In the ongoing GHSG HD17 trial the standard arm of involved-field radiation therapy following chemotherapy, regardless of response, is compared against the experimental arm of involved-node radiation therapy in patients who have achieved a complete response to chemotherapy.

Finally, the question of omitting radiation therapy has been addressed by several randomized trials, most of which showed a benefit in disease-free survival but not overall survival benefit with the addition of radiation therapy. However, a meta-analysis conducted by the Cochrane Haematological Malignancies Group[8] included five randomized controlled trials that compared chemotherapy alone with identical chemotherapy combined with radiotherapy for patients with stage I-II Hodgkin lymphoma and found a highly significant overall survival benefit with the addition of radiation therapy (hazard ratio [HR], 0.4; $P < 0.00001$). Picardi et al[9] conducted a randomized trial that included patients with stage I-IV disease with disease sites of greater than 5 cm, evaluating whether radiation therapy can be safely eliminated if a complete response by PET scan is achieved after six cycles of vinblastine, etoposide, bleomycin, epirubicin, and prednisone (VEBEP). A significant event-free survival benefit was found with the addition of radiation therapy in this carefully selected group of patients (96% versus 86%, $P = 0.03$). One key criticism of this trial is the use of suboptimal chemotherapy rather than the standard ABVD. Several ongoing randomized trials are addressing the question of whether radiation therapy can be eliminated in early-stage Hodgkin lymphoma patients with a complete response or early complete response by PET to ABVD, including the European Organization for Research and Treatment of Cancer/Groupe d'Etude des Lymphomes de l'Adulte (EORTC/GELA) H10 trial, the RAPID trial, and the GHSG HD16 trial. Details of the trial designs are summarized in Table 56-1.

Early-Stage Non-Hodgkin Lymphoma

Non-Hodgkin Lymphoma is a heterogeneous disease. The two most common histologic subtypes are diffuse large B-cell lymphoma and follicular lymphoma, accounting for three-quarters of all cases of non-Hodgkin lymphoma. Radiation therapy plays an important role in both of these subtypes of non-Hodgkin lymphoma in patients with limited-stage disease. Another subtype of non-Hodgkin lymphoma in which the role of radiation therapy is increasingly recognized is marginal zone lymphoma or mucosa-associated lymphoid tumor (MALT).

Stage I-II Diffuse Large B-Cell Lymphoma

Historically patients with localized diffuse large-cell lymphoma, many of whom were staged surgically, were treated with radiation therapy alone, with a cure rate of less than 50%. Since 1980, a doxorubicin-based combination chemotherapy regimen with or without radiation therapy has become the treatment of choice, yielding significantly improved relapse-free survival and overall survival rates (see box on Preferred Treatment for Early-Stage Non-Hodgkin Lymphoma). Table 56-2 summarizes randomized trials that compare chemotherapy alone versus combined modality therapy in patients with stage I-II aggressive non-Hodgkin lymphoma. These trials vary considerably in baseline patient and disease characteristics[10-13] and are associated with a number of limitations. Two of the trials used

Preferred Treatment for Early-Stage Non-Hodgkin Lymphoma

Early-Stage Diffuse Large B-Cell Lymphoma Treated With Combined Modality Therapy

Use of Involved Fields

- After a complete remission achieved with six to eight cycles of CHOP or R-CHOP: 36 Gy if initial bulky disease; 30 Gy for the remainder of patients
- After three to four cycles of CHOP or R-CHOP: 35 to 40 Gy
- After a partial remission: 40 Gy

Early-Stage Follicular Grade 1 and 2 Lymphoma

Use of Involved or Regional Fields

Carefully planned radiation therapy to limited fields with modest doses can significantly reduce the risk for significant damage to the marrow reserve, the risk for developing a treatment-related malignancy, and the risk for long-term toxicity to other normal tissues such as the salivary glands, lungs, heart, kidneys, and bowel.

The recommended dose is 30 to 36 Gy with a boost to areas of initial involvement to 36 to 40 Gy. Bulky disease should be treated to the upper end of the range; 30 to 36 Gy should suffice for smaller-volume disease.

Early-Stage Mucosa-Associated Lymphoid Tumor or Extranodal Marginal Zone Lymphoma

Use of Radiation Therapy to Involved Nodal Regions or Extranodal Sites

Doses of 30 Gy result in a near 100% local control rate. Although there are limited data with lower doses such as 25 Gy (except for orbital MALT), local control rates can also be high with this dose. This should allow for modification of dose in settings where the risk for injury to normal tissue is higher (orbit, salivary glands).

Although there are high complete response rates with chemotherapy for marginal zone lymphoma, there is little evidence that it is curative. Therefore, outside of clinical trials, chemotherapy should be reserved for patients with stage III-IV disease. Asymptomatic individuals with generalized disease may be considered for observation, similar to patients with generalized follicular lymphoma.

abbreviated chemotherapy in the radiotherapy-containing arms[10,12] and are thus more suited to address alternatives to intensive chemotherapy alone, rather than to specifically address the role of radiation therapy after chemotherapy. Other shortfalls of these trials include inadequate chemotherapy,[13] limited power,[11] poor compliance to assigned treatment arms,[11] and suboptimal radiotherapy quality control. Most importantly, none of the trials included the use of rituximab in combination with doxorubicin-based chemotherapy and therefore did not address the role of consolidation radiation therapy when used in conjunction with current standard systemic therapy.

More recently retrospective studies that included mostly patients treated with rituximab, cyclophosphamide, hydroxydaunomycin, vincristine (Oncovin), and prednisone (R-CHOP) chemotherapy have shown a significant advantage to the addition of consolidation radiation even in patients with a complete response to chemotherapy.[14] An ongoing prospective randomized trial conducted by the German High-Grade Non-Hodgkin's Lymphoma Study Group (DSHNHL) may clarify the role of radiation therapy in the rituximab era and identify the subgroup of patients who may benefit from consolidation radiation therapy. In this study, patients with nonbulky disease are randomized to R-CHOP-21 alone versus R-CHOP-14 alone. Patients with bulky disease and/or extranodal disease are randomized to one of four arms: R-CHOP-21 alone, R-CHOP-14 alone, R-CHOP-21 followed by radiation therapy if a complete response is achieved, and R-CHOP-14 followed by radiation therapy if complete response is achieved.

Stage I-II Follicular Lymphoma

A number of studies have shown that radiation therapy alone can result in long-term cure in 30% to 40% of patients with stage I-II follicular grade 1-2 lymphoma. Several large series showing the treatment for limited-stage follicular lymphoma are shown in Table 56-3.[15-24] The median radiation doses vary from 30 to 40 Gy in eight of the nine series with the two largest series reporting a median dose of 35 Gy.[15,16] Recurrences within the treatment field range from 0% to 13.8% with higher percentages occurring in patients with bulky disease or who receive a radiation dose of less than 30 Gy. A variety of field sizes have been used, ranging from total-nodal, extended-field, regional-field, to involved-field irradiation. A recent retrospective explored further reducing the size of the radiation field to involved-node radiation therapy, defined as coverage of the involved lymph node(s) with margins of 5 cm or less, compared with regional-field radiation therapy for patients with stage I-II follicular lymphoma.[25] After multivariable analysis, the treatment field size did not significantly predict for disease specific–, progression free–, and overall survival outcome. As discussed later under Radiation Treatment Fields in Hematologic Malignancies, the definition of involved-node radiation therapy varies from group to group and currently remains in evolution.

Although radiation therapy alone is considered potentially curative therapy for patients with stage I-II follicular lymphoma, a multicenter, longitudinal, observational study from the United States showed that only 23% of patients with stage I disease at presentation received radiation therapy alone, suggesting that this well-established, potentially curative treatment approach is currently underutilized.

Stage I-II Mucosa-Associated Lymphoid Tumor Lymphoma

The indolent extranodal marginal zone or MALT lymphomas most commonly involve the gastrointestinal tract, salivary glands, breast, thyroid, orbit, conjunctiva, skin, and lungs. Because this subtype of lymphoma tends to remain localized for long periods of time, local treatment (surgery or local/regional irradiation) is effective at achieving long-term control and possible cure. Tsai et al[26] reported 77 patients with stage I-II marginal zone lymphoma. The majority were treated with radiation therapy, and the remaining patients were treated with surgery with or without systemic therapy. For those who received radiation therapy, the median radiation dose was 30 Gy. After a median follow-up of 61 months, the 5-year progression-free survival, freedom from treatment failure, and overall survival rates were 76%, 78%, and 91%, respectively. Patients who received radiation therapy had significantly greater local control (100% versus 50%, $P = 0.001$), freedom from treatment failure (81% versus 50%, $P = 0.0004$), and progression-free survival (79% versus 50%, $P = 0.002$)

rates. More recent data suggest that doses lower than 30 Gy may be adequate, especially to the orbit, where the use of limited doses may avoid damage to the lacrimal glands. Goda et al,[27] from Princess Margaret Hospital, reported the long-term results of 167 patients with stage I-II MALT lymphoma who received involved-field radiation therapy. The median dose to nonorbital sites was 30 Gy and that to the orbit was 25 Gy. After a median follow-up of 7.4 years, the 10-year rate of local control was 95%, cause-specific survival was 98%, disease-free survival was 68%, and overall survival was 87%. Nine of 31 (29%) patients developed disease recurrence in the contralateral paired organ. These results suggest that local control can be achieved with lower doses of radiation such as 25 Gy, which should allow for modification of the dose in settings where the risk for damaging normal tissues is especially high (orbit, salivary glands).

Leukemia and Myeloma

The primary means of treating the leukemias and multiple myeloma is systemic therapy. The role of radiation therapy in the overall management of these patients in complex and depends on the overall treatment plan. Therefore only a few of the principles of radiation therapy are discussed.

Acute Lymphoblastic Leukemia and Lymphoma

The predominant role for radiation therapy is for central nervous system prophylaxis of leukemia and lymphoma patients given the pattern of relapse in particular disease types. The standard dose for adult patients is 1800 cGy, although in the pediatric population, lower doses are being evaluated, because of concerns of delayed neurocognitive dysfunction. Radiation therapy doses of 2400 to 3000 cGy are occasionally used for palliation or for salvage therapy in patients with central nervous system or testicular relapses.

Solitary Plasmacytomas and Multiple Myeloma

Solitary plasmacytomas may occur in bone or in soft tissue. Radiation therapy produces long-term local control of over 80%. The precise dose needed has been debated, but at least 4000 to 5500 cGy should be administered.

Radiation therapy is often used as palliation for patients with bony lesions from multiple myelomas. A typical palliative regimen might be 3000 cGy over 2 weeks. The dose and fractionation must be tailored to the clinical setting. A patient with newly diagnosed multiple myeloma who is expected to live many years should be treated with a higher total dose and a lower dose per fraction. Lesions near the spinal cord should be treated with a dose equivalent to 4000 cGy because a local failure would be difficult to retreat.

RADIATION TREATMENT FIELDS IN HEMATOLOGIC MALIGNANCIES

The radiation field designs that have been used in the past or are currently employed in lymphoma therapy include the following:

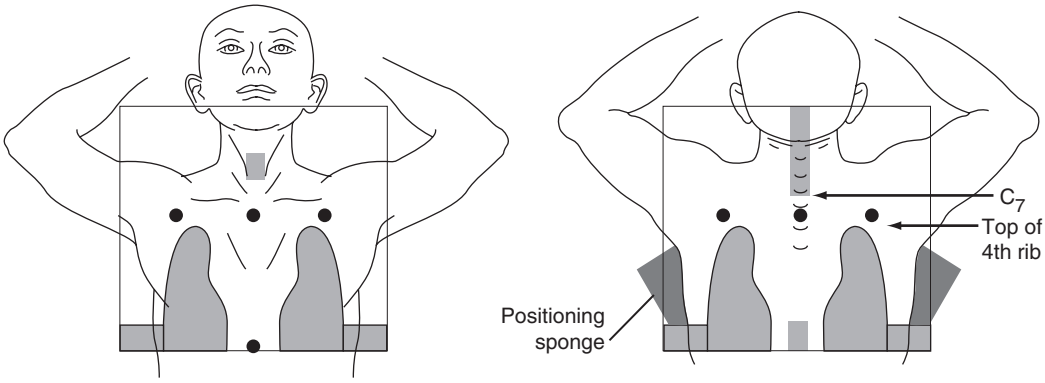

Figure 56-2 A TYPICAL MANTLE IRRADIATION FIELD.

1. Mantle field: This treatment field and its variations have been the most commonly used treatment field in patients with supradiaphragmatic Hodgkin lymphoma. It includes the submental, cervical, supraclavicular and infraclavicular, axillary, hilar, and mediastinal lymph nodes (Fig. 56-2). The dose inhomogeneity in a mantle field is a result of variation in separation of a patient's upper body and the irregularly contoured lung blocks that affect the scatter doses to different areas within the field. For instance, the dose to the cervical and axillary regions tends to be higher because of decreased patient thickness in the soft tissue of the neck and axilla, whereas the dose toward the inferior border of the mantle field tends to be lower, because of the thicker separation in that region of the body as well as loss of scatter doses due to the adjacent lung blocks. Some of the techniques that are employed to minimize dose inhomogeneity include the use of an extended source-to-node distance of 110 cm or greater, and by the use of higher-energy megavoltage machines. However, the energy used is limited by the need to ensure adequate doses to superficial nodes, which can fall within the "build-up" regions of the radiation beams and be potentially underdosed if energy higher than 6 MV is used.
2. Mantle and para-aortic (MPA) ± splenic field: Also known as subtotal nodal or lymphoid irradiation, the para-aortic lymph nodes in addition to the mantle field are treated. The spleen is included in the treatment field in patients who do not undergo surgical staging and splenectomy.
3. Total nodal irradiation (TNI) or total lymphoid irradiation: This encompasses most of the lymphoid tissue, with the addition of a pelvic field to the mantle and para-aortic field. However, other nodal groups, such as the brachial, epitrochlear, popliteal, sacral, and mesenteric nodes are not specifically included in the TNI field. MPA radiation therapy and TNI are used less frequently today because of the widespread use of chemotherapy.
4. Inverted-Y field: This is used in patients presenting with infradiaphragmatic lymphoma and includes treatment to the para-aortic and pelvic lymph nodes.
5. Involved-field radiation: By definition, this includes at least the entire lymph node group but may also contain the contiguous nodes. For example, in a patient presenting with an enlarged cervical lymph node, an involved-field treatment would include the entire ipsilateral cervical chain and the supraclavicular region, because these nodes are considered one region (Fig. 56-3). In a patient with mediastinal involvement, the field would include the mediastinal, hilar, subcarinal, and medial supraclavicular nodes. Although the hilar nodes are scored separately traditionally, the hilar and subcarinal nodes are included in the mediastinal field (Fig. 56-4). In addition, the medial supraclavicular nodes are included in order to cover the upper mediastinum (top of T1).

The radiation field designs employed in lymphoma therapy have evolved substantially over the last several decades, from total nodal irradiation to subtotal nodal irradiation (or MPA radiation therapy)

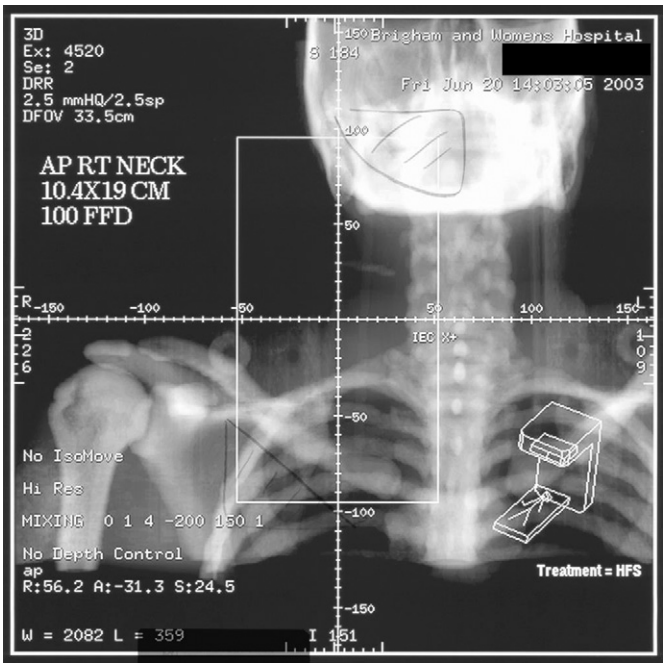

Figure 56-3 INVOLVED FIELD TO THE CERVICAL AND SUPRACLAVICULAR NODAL CHAIN IN A PATIENT WITH CERVICAL NODE INVOLVEMENT ONLY.

to involved-field radiation therapy. The definition of involved-field radiation therapy was described in detail with site-specific examples by Yahalom and Mauch in 2002, although this was mostly based on 2D planning, relying on the use of bony landmarks to determine field setup. In recent years, there has been an increasing effort to further reduce radiation field size to include nodes. However, the definition of involved-node radiation therapy differs from group to group,[28-30] including inconsistencies on the expansion from clinical target volume to planning target volume, which ranges from 1 cm to 5 cm, on the requirement of use of prechemotherapy PET scanning to determine the clinical target volume, and treatment techniques. As summarized in Table 56-4, there is considerable variation in the definition of involved-node radiation therapy by the EORTC/GELA,[28] GHSG,[29] and British Columbia group,[30] and there is a need to standardize this definition. Outside of a clinical trial, the optimal treatment field may be a modified form of involved-field treatment, tailored to the tumor site and the surrounding normal tissues. For example, in patients with low cervical and supraclavicular involvement, the upper neck can be excluded to spare salivary gland function; in patients with mediastinal involvement only, the hila can be excluded to limit exposure to the heart, lungs, and breasts.

Table 56-4 Definitions of Involved-Node Radiation Therapy

Pretreatment Evaluation	CTV	GTV	PTV	Technique
EORTC/GELA				
CT in treatment position if possible PET in treatment position strongly recommended	If CR/CRu, initial volume of LN with exclusion of normal displaced structures (e.g., muscles, blood vessels) For mediastinum, CTV is normal mediastinum with length of CTV based on prechemotherapy volume If PR, CTV definition same as CR/CRu	If CR, not applicable If PR, postchemotherapy volume	If CR/CRu, 1 cm isotropic margin of CTV If PR, PTV1: CTV + 1 cm isotropic margin PTV2: GTV + 1 cm isotropic margin PTV should receive 95%-107% of prescribed dose	3D, 4D, IMRT, if APPA, field size needs to be ≥5 × 5 cm If LN >5 cm apart, use separate fields; if ≤5 cm, then encompass in same field
GHSG				
Examination by radiation oncologist CT of neck/C/A/P in treatment position PET/CT in treatment position if possible	Same as EORTC/GELA	Not specified	2-cm axial and 3-cm cranial caudal expansion of CTV (if necessary, can be reduced to 1-1.5 cm if close proximity to critical structures) For mediastinum, 1 cm axial and 2 cm cranial caudal)	Not specified
BCCA (INRT≤5 CM)				
Not specified	Prechemotherapy and postchemotherapy nodal volume, restricted by postchemotherapy anatomic limits	Not specified	Margin from CTV to field edge: 1.5-5 cm	CT planning not mandatory

FUTURE DIRECTIONS

Over the last several decades, tremendous advances have been made in the field of radiation oncology. The role of radiation therapy in the management of patients with hematologic malignancies has evolved, as systemic therapy options have improved, response assessment has become more reliable with functional imaging, and conformal radiation treatment planning and delivery have become more available. Future efforts include refining indications for radiation therapy in various settings, based on initial disease characteristics as well as response to treatment. In addition, optimal radiation doses and treatment fields need to be standardized. Finally, modern radiation therapy techniques including IMRT, image-guided therapy, four-dimensional radiation therapy, and dose painting may be applied to selected cases to further improve tumor targeting while sparing normal tissues.

CHAPTER 57

PATHOBIOLOGY OF ACUTE MYELOID LEUKEMIA

Michael Andreeff and Alfonso Quintás-Cardama

Human leukemias have posed unique clinical and conceptual challenges since their initial identification by Rudof Virchow 150 years ago. They continue to elicit fascination by those who study their biology, molecular genetics, and clinical presentation and have proven to be sensitive to chemotherapy, but are also incurable, depending on their cytogenetics and molecular genetics. This chapter summarizes our present, evolving knowledge of acute myeloid leukemia (AML) molecular pathophysiology.

Acute leukemias are clonal disorders that arise from hematopoietic progenitors developing either in the lymphoid or myeloid pathway or from primitive stem cells with multilineage potential. The genesis of human myeloid leukemia involves the deregulation of differentiation and maturation programs of the hematopoietic myeloid lineage that develops from primitive stem progenitor cells with multilineage potential. Myeloid leukemias have been linked to acquired somatic chromosomal translocations or inversions. These genomic rearrangements alter gene expression patterns that result in subversion of the programs regulating cell proliferation, differentiation, and survival. These changes are believed to determine the process of leukemic transformation,[1] a hypothesis has been supported by results obtained from gene manipulation studies in murine models.[2,3]

Chronic myeloid leukemia (CML) was the first cancer associated with a specific chromosomal abnormality. This aberrancy, first identified as a minute chromosome, is now known as the Philadelphia chromosome, which results from the t(9;22) balanced reciprocal translocation. The molecular consequence of the Philadelphia translocation is the generation of the oncogene *BCR-ABL1* that encodes the chimeric BCR-ABL protein with constitutive kinase activity. Extensive structural biology studies prompted the investigation of rationally designed small molecules that target the tyrosine kinase activity of the BCR-ABL kinase for the treatment of CML. The impressive results obtained with the first agent of this kind, imatinib mesylate, laid the foundation for the extensive development of targeted therapies of other leukemias and solid tumors. However, these initial results were partially offset by the realization that most patients receiving imatinib harbor residual disease[4] and that responses in patients with CML in accelerated phase (AP) or blastic phase (BP), when they occur, are generally short lived.[5] These shortcomings have propelled further studies to understand the mechanisms of resistance to tyrosine kinase inhibitor (TKI) therapy and the development of novel agents to override these limitations.

Acute myeloid leukemias are clinically characterized by accumulation of immature blastic cells that exhibit uncontrolled growth, lack normal differentiation, and exhibit much decreased apoptosis. The different AML phenotypes are classified, mostly by morphologic criteria, into subtypes according to the predominance of a particular myeloid lineage. The acquired somatic mutations that underlie the molecular pathogenesis of AML target an ample group of transcription factors and signaling pathways that result in the abrogation of orderly myeloid differentiation and cell death that all control population size. The current paradigm of AML pathogenesis implies a multistep process that involves at least two different types of genetic alterations. One type of alterations involves typically the deregulation of transcription factors that modulate hematopoietic development. Frequently, these arise from chromosomal translocations, and the resulting chimeric fusion proteins impair differentiation of a particular myeloid lineage, thus specifying the AML subtype. A second class of alterations affects intracellular signaling involved in cell survival and proliferation, such as protein receptors with tyrosine kinase activity.

Over 3 decades, investigation of clonal chromosomal abnormalities in leukemic cells obtained from patients with myeloid leukemia and the development of transgenic mouse models have been used to deconstruct the molecular pathways leading to leukemic transformation. These approaches have impacted our understanding of the molecular changes involved in the pathogenesis of these disorders and have uncovered potential therapeutic targets. This chapter describes the current state of knowledge of the molecular events involved in the pathogenesis of both myeloid leukemias.

PHILADELPHIA-CHROMOSOME LEUKEMIAS

Myeloid leukemias (both acute and chronic) result from the neoplastic transformation of a hematopoietic stem cell. The hallmark genetic abnormality driving the pathogenesis "Philadelphia chromosome" leukemias is the balanced translocation t(9;22)(q34;q11), which cytogenetically results in the Philadelphia chromosome[6,7] and molecularly gives rise to the *BCR-ABL1* hybrid gene.[8,9] The *BCR-ABL1* gene encodes a protein kinase, BCR-ABL, which is constitutively activated in CML. Classically, CML has been described as a disease that evolves in three phases. Most patients are diagnosed in the chronic phase (CP), characterized by overproduction of immature myeloid cells and mature granulocytes in the bone marrow (BM) and peripheral blood. Left untreated, most patients progress to blast phase, characterized by a peripheral blood or BM blast percentage of over 30%, usually preceded by an accelerated phase.[10] The estimated risk of transformation to BP is 5% to 10% per year during the first 2 years after diagnosis, but the annual progression rate increases to up to 20% to 25% thereafter.[10,11] CML in BP is characterized by remarkable resistance to chemotherapeutic drugs.

The BCR-ABL1 Oncogene

The *ABL1* gene is the human homologue of the v-*abl* oncogene carried by the Abelson murine leukemia virus (A-MuLV).[12] *ABL1* encodes the 145-kd nonreceptor tyrosine kinase ABL that localizes at several subcellular sites, including the nucleus, cytoplasm, mitochondria, the endoplasmic reticulum, and the cell cortex, where it interacts with a large variety of cellular proteins, including signaling adaptors, other kinases, phosphatases, transcription factors, and cytoskeletal proteins.[13] ABL is expressed in most tissues, and its structure is organized in functional domains.[14,15] In turn, *BCR* encodes a protein with serine-threonine kinase activity. The fusion of the BCR and ABL1 genes results in the activation of the c-*ABL1* protooncogene to its oncogenic form.[16,17] Several experimental models, such as *BCR-ABL1*–expressing $CD34^+$ cells in culture [18,19] or retrovirally transduced *BCR-ABL*-positive mouse cells,[20-22] have demonstrated that the *BCR-ABL1* is central to the pathogenesis of CML. Moreover, mice expressing a *BCR-ABL1* isoform with a point mutation in the adenosine triphosphate (ATP)–binding pocket of ABL, which results in

inactivation of the kinase activity, do not develop leukemia even when the mutant transcript is expressed in long-term repopulating hematopoietic stem cells. These findings ultimately corroborate that ABL kinase activity is essential for *BCR-ABL1*-mediated leukemogenesis in vivo[15,22] and provide the rationale for the targeted use of TKIs for the treatment of CML. However, unlike other fusion oncogenes such as *MLL-ENL* or *MOZ-TIF2*, *BCR-ABL1* can transform hematopoietic stem cells but cannot transform committed progenitors lacking the capacity of self-renewal.[23] This has been shown in experiments in which flow-sorted populations of common myeloid progenitors and granulocyte-monocyte progenitors were transduced with either *MOZ-TIF2* or *BCR-ABL1*.[23] Unlike BCR-ABL1–transduced progenitors, those expressing MOZ-TIF2 could be serially replated in methylcellulose cultures and resulted in AML in vivo that could be serially transplanted.[23]

The breakpoints within the *ABL1* gene at 9q34 takes place within a large area that spans more than 300 kilobases (kb) at its 5′ end and can occur upstream of exon Ib; downstream of exon Ia; or, more frequently, between exons Ib and Ia.[24] In contrast, breakpoints within *BCR* map to three distinct areas known as *breakpoint cluster regions*. In most patients with CML, and in approximately one-third of those with Philadelphia chromosome–positive B-cell acute lymphoblastic leukemia (B-ALL), the break occurs within a 5.8-kb area spanning BCR exons e12-e16 (formerly called b1-b5), referred to as the *major breakpoint cluster region* (M-*bcr*). A fusion transcript with either b2a2 or b3a2 junctions is possible because of alternative splicing, thus giving rise to a 210-kd protein ($p210^{BCR\text{-}ABL1}$).[25] In two-thirds of patients with Philadelphia chromosome–positive B-ALL and in rare cases of CML, the *BCR* breakpoint localize to an area of 54.4 kb between exons e2′ and e2, termed the *minor breakpoint cluster region* (m-*bcr*), generating an e1a2 transcript that translates into a 190-kd protein ($p190^{BCR\text{-}ABL1}$). It has been suggested that patients with CML carrying $p190^{BCR\text{-}ABL1}$ may have a worse prognosis than those expressing the classical $p210^{BCR\text{-}ABL1}$ isoform.[26] A third breakpoint cluster region (μ-*bcr*), downstream of exon 19, has been occasionally identified in patients with CML, giving rise to a 230-kd fusion protein ($p230^{BCR\text{-}ABL1}$), which has been associated with a phenotype similar to that of chronic neutrophilic leukemia.[27] The leukemogenic potential of all three transcripts has been demonstrated in murine models. However, the tyrosine kinase activity of the different BCR-ABL variants differs significantly, with $p230^{BCR\text{-}ABL1}$ having the least activity and conferring only partial growth factor independence relative to the potent protein kinase $p190^{BCR\text{-}ABL1}$,[28,29] which may explain the more benign clinical course of patients with $p230^{BCR\text{-}ABL1}$.

Anatomy and Autoregulation of the BCR-ABL Protein

The N-terminus of BCR-ABL members consists of the "Cap" region, which is present in two different isoforms generated by alternative splicing of the first exon, termed 1a and 1b. ABL 1b contains a C_{14} myristoyl saturated fatty acid moiety covalently linked to the N-terminus and is expressed at higher levels than type 1a, which is not myristoylated. ABL also contains a tyrosine kinase domain that is preceded by a Src-homology-2 (SH2) and an SH3 domain. These three domains or motifs are highly conserved both in terms of sequence and spatial organization. Moreover, ABL has a long C-terminus extension, known as the last exon region, which contains protein–protein interaction sites responsible for the diverse subcellular localizations and functions of the protein.[13] The last exon region contains four proline-rich SH3 motifs that function as binding sites for the SH3 domains of adaptor proteins such as Crk, Grb2 (growth-factor-receptor-bound 2) and Nck,[30,31] a DNA-binding domain, an actin-binding domain, three nuclear localization signals, and one nuclear export signal, which allows c-Abl to shuttle between the nucleus and the cytoplasm in response to environmental stimuli.

BCR also exhibits a complex architectural modularity at the N-terminus highlighted by the presence of coiled-coil oligomerization domain, a serine/threonine kinase domain, a Dbl/CDC24 guanine-nucleotide exchange factor homology domain and a pleckstrin homology domain, a putative calcium-dependent lipid binding site, and a RAC guanosine triphosphatase-activating protein domain. Also in BCR, the tyrosine residue 177 (Y177) serves as docking site for growth factor receptor-bound protein 2 (GRB2), GRB10, 14-3-3, and the ABL proteins, through its SH2 domain.[15]

In simple terms, the Ph chromosome causes the replacement of the endogenous autoregulatory domain of ABL with erroneous coding sequences from BCR. In this novel protein, BCR-ABL, the tight temporal and spatial regulation of ABL is lost, resulting in constitutively high levels of tyrosine kinase activity. In *BCR-ABL1*–positive cells, both SH3 and SH2 domains in ABL function as an autoinhibitory structure that maintains the kinase domain in an off state.[32-34] Crystal structures of ABL have shown that the myristoyl modification at the extreme end of the N-terminal segment of ABL 1b engages with the C-terminal lobe of the ABL catalytic domain. This interaction induces conformational changes that facilitate the docking of the SH2 and SH3 domains onto the kinase domain[32,35] in a manner that closely resembles the inactive conformation of SRC.[13,36-38] Thus, binding of the myristoyl group to the pocket in the C-terminal lobe appears essential for adopting an autoinhibited conformation of ABL 1b, and forms of ABL 1b lacking the myristoyl group show constitutive tyrosine kinase activity.[13] The elements in ABL 1a that replace the function of the myristoyl group of ABL 1b have not been elucidated yet. In structures of inactive BCR-ABL, the SH2 and SH3 domains stabilize an inactive conformation of the kinase domain in which a prominent α-helix (helix αC) in the N-terminal lobe (N-lobe) of the kinase is displaced inwardly toward the active site, forming an ion pair between the conserved residues Lys271 and Glu286 residues[37] while the SH2 domain remains tightly bound to the C-lobe of the kinase. In this conformation, the rotation of the helix αC results in the displacement of important catalytic residues out of the active site, which precludes the access of ATP and the peptide substrate to the active site.[13] Of interest, several structural analyses have shown that the last exon region of ABL may be dispensable for SH3 domain–dependent autoinhibition in vitro.[34,39] In addition, ample evidence indicates that BCR is an important mediator of ABL deregulation. X-ray crystal structural analysis of the oligomerization domain of BCR-ABL (residues 1–72 or $BCR_{1–72}$), which includes the coiled-coil domain ($BCR_{30–65}$), has shown that two monomers associate in an antiparallel dimer that stacks to form a tetramer.[40] It is tempting to hypothesize that the fusion of BCR activates the activity of the ABL kinase via dimerization-mediated autophosphorylation of BCR-ABL molecules. Furthermore, the kinase activity, transformation, phosphorylation of tyrosine residues in the activation loop of the catalytic domain, and the leukemogenic potential of BCR-ABL are remarkably impaired by mutations of the coiled-coil domain secondary to impairment of oligomerization.[41] Accordingly, transformation by BCR-ABL devoid of the coiled-coil domain of BCR can be partially restored by deletion of the SH3 domain.[42]

Signaling Pathways Downstream of BCR-ABL

The leukemogenic activity of the BCR-ABL fusion tyrosine kinase relies upon its ability to promote gain-of-fitness changes that translate into abrogation of growth-factor/adhesion dependence, morphologic transformation, growth advantage, and enhanced proliferation.[20] These effects result from the activation of numerous downstream effector pathways by the BCR-ABL oncoprotein. The BCR autophosphorylation site Y177 is essential for *BCR-ABL1*–mediated leukemogenesis.[43,44] *BCR-ABL1* oncogenes in which Y177 is mutated to phenylalanine (Y177F) largely abolish GRB2 binding and abrogate BCR-ABL–induced RAS activation.[45] Therefore, despite preservation of the kinase activity of ABL, *BCR-ABL1-Y177F* impairs the transformation of primary BM cultures.[45] In a stem cell transplantation (SCT) model of CML, transfection of the mutant *BCR-ABL1-Y177F* results in a remarkably reduced ability to induce a myeloproliferative disorder (MPD) in mice.[45] The Y177 residue constitutes a high-affinity docking site for the SH2 domain of growth factor

receptor–bound protein 2 (GRB2). GRB2, which in turn, recruits SOS (a guanine-nucleotide exchanger of *RAS*) that activates RAS,[15] and the scaffold adapter GRB2-associated binding protein 2 (GAB2) through its SH3 domain.[15] Tyrosine phosphorylation of GAB2 in *BCR-ABL1*–transformed cells requires Y177 of BCR-ABL and the GRB2 SH3 binding site in GAB2.[46] Therefore, BCR-ABL–induced GAB2 phosphorylation is mediated by a GRB2-GAB2 complex. This interaction is required for the full activation of the phosphatidylinositol 3-kinase (PI3K)–AKT and the RAS-ERK pathways as well as for the optimal proliferation and migration of Ba/F3 cells in response to BCR-ABL. As a consequence, BCR-ABL cannot transform primary myeloid cells from *GAB2*$^{(-/-)}$ mice.[46] The interaction of GRB2 and GAB2 is also critical for the activation of SHP2 (also known as PTPN11), which is required for the normal activation of the RAS extracellular signal-regulated kinase pathway that most receptor tyrosine kinases signal through.[15]

BCR-ABL also phosphorylates the SRC family kinases (SFKs) HCK, LYN, and FGR. Phosphorylation of HCK leads to recruitment of signal transducer and activation of transcription 5 (STAT5),[15,47] which results in dimerization and translocation of STAT5 molecules to the nucleus, where they modulate gene transcription through binding to cognate DNA sequences. However, the leukemogenic role of STAT5 in CML has been controversial. BCR-ABL–induced STAT5 phosphorylation and activation may occur either or indirectly through phosphorylation by Janus kinase 2 (JAK2) [48] or by SFKs.[49] In earlier experiments, retroviral transduction of *BCR-ABL1* into BM still induced a CML-like MPD in *STAT5a*$^{(-/-)}$*STAT5b*$^{(-/-)}$ mice.[50] The role of STAT5 has been recently revisited.[51,52] Inactivation of STAT5 with siRNA in human samples from patients with CML impairs Philadelphia chromosome–positive myeloid colony formation. Also, fetal liver hematopoietic progenitors from mice that have the entire *STAT5ab* locus deleted were incapable of generating leukemia in recipient mice after retroviral transduction with *BCR-ABL1*.[51] Additionally, BCL-X, which is repressed by the transcription factor interferon consensus sequence binding protein (ICSBP),[53] is transcriptionally activated by STAT5 in CML.[54] A series of knock-out mice studies have also shown the dispensability for *BCR-ABL1*–mediated leukemogenesis of several other factors such as CBL, interleukin-3 (IL-3), and granulocyte-macrophage colony-stimulating factor (GM-CSF).[55,56] Recently, it has been demonstrated that *BCR-ABL1* retrovirus-transduced BM from mice lacking the SFKs HCK, LYN, and FGR efficiently induced CML but not B-ALL, suggesting a prominent role these kinases in Philadelphia chromosome–positive lymphoid malignancies.[57] In keeping with these observations, ablation of LYN by siRNA in primary CML cells impaired leukemic cell viability and colony formation in primary cells from patients with Philadelphia chromosome–positive CML in lymphoid BP but had less effect on myeloid BP cells.[58] Interestingly, BCR-ABL–activated SFKs, which may be essential for transition to lymphoid BP, remain fully active in imatinib-treated mouse leukemic cells, suggesting an additional benefit of agents with potent anti-SFK activity (e.g., dasatinib) for patients with CML in lymphoid BP and Philadelphia chromosome–positive B-ALL.[59]

Although the individual contribution of some downstream elements activated by BCR-ABL may appear negligible when evaluated individually in knock-out systems, there is evidence supporting a cooperative role of some of these factors in the pathogenesis of CML. When *BCR-ABL1*–positive K562 cells were induced to express dominant negative forms of RAS, PI3K, or STAT5, marked apoptosis was observed in cells coexpressing two of the three dominant negative mutants in any combination.[60] These results suggest that a cooperative interplay among these factors is necessary for the full realization of the leukemogenic potential of BCR-ABL kinase.

It has been recently reported that mice deficient in the enzyme 12/15-lipoxygenase (12/15-LO) develop a MPD that progresses to transplantable leukemia independent from ABL dysregulation.[61] Cells isolated from chronic stage 12/15-LO-deficient mice *(Alox15)* exhibit increased activation of the PI3K–AKT pathway as well as hyperphosphorylation of the transcription factor interferon consensus sequence binding protein (ICSBP), translating into increased BCL-2 expression and leukemic cell survival.[61] ICSBP is a tumor suppressor and a negative regulator of granulocyte differentiation.[62] Forced expression of ICSBP inhibited the *BCR-ABL1*–induced CML-like disease in vivo.[63] Notably, all of the effects observed in *Alox15* mice were reversed upon treatment with a PI3K inhibitor. 12/15-LO expression suppressed the growth of a human CML-derived cell line, which in aggregate, suggests that 12/15-LO is an important suppressor of MPD by virtue of its PI3K-dependent regulation of ICSBP and their downstream target genes in vivo.[61]

JUNB is a component of the activator protein 1 family of transcription factors that has been shown to act as a tumor suppressor in myeloid cells,[64] antagonizing the RAS downstream target JUN, thus inhibiting cell proliferation and survival. Modifications of *JUNB* expression may have a role in the pathogenesis of CML. Transgenic mice specifically lacking *JUNB* in the myeloid lineage (*JunB*$^{-/-}$Ubi-*JunB* mice) developed an MPD that closely resembled human CML, beginning at 4 months of age, including progression to BP in 16% of mice.[65,66] Furthermore, only *JUNB*-deficient long-term self-renewing hematopoietic stem cells from diseased mice were able to induce CML-like disease in recipient mice after transplantation.[66]

Some of the elements involved in BCR-ABL signal transduction provide the rationale for the development of targeted therapies for patients with CML.

Transformation to Blast Phase or Acute Leukemia

Evolution of CML to BP is characterized by the development of a marked degree of resistance to treatment that is difficult to overcome by currently available therapies. The mechanisms responsible for the transition from the CP of CML to the BP remain poorly understood. This has been caused, at least in part, by the lack of adequate animal models of *BCR-ABL1*–induced leukemia with a long myeloproliferative phase necessary for assessing mechanisms of disease progression. Although little is known about the mechanisms involved in transformation to BP, continued expression or activity of BCR-ABL kinase and the acquisition of additional cytogenetic and molecular changes are observed in the majority of patients with CML during evolution to BP.[67] Approximately 80% of patients with CML develop additional nonrandom cytogenetic aberrancies in Philadelphia chromosome–positive metaphases. This phenomenon is known as *clonal evolution* and reflects the genetic instability frequently associated with advanced stages of the disease.[68]

Clonal evolution is believed to play a prime role in CML progression. The most frequent secondary cytogenetic abnormalities encountered in patients with clonal evolution are trisomy 8 (34%), isochromosome 17 (20%), and duplicate Ph chromosome (38%),[69] which have been linked to c-*Myc* overexpression, loss of 17p, and *BCR-ABL1* overexpression, respectively.[70-72] Other cytogenetic aberrancies, such as trisomy 19, trisomy 21, trisomy 17, and deletion 7, have been identified in fewer than 10% of cases of clonal evolution.[73] These genetic lesions are more frequently associated with myeloid than with lymphoid CML-BP. In addition, 10% to 15% of patients with CML present with deletions of the derivative chromosome 9, which may be a reflection of genomic instability leading to more rapid progression to BP than those lacking this abnormality.[74] The detrimental prognosis conferred by deletions of the derivative chromosome 9 appears to be offset by imatinib therapy.[75] Other cytogenetic abnormalities have been detected in Philadelphia chromosome–negative metaphases of patients with CML with an incidence ranging from 2% to 17% and have been occasionally linked to development of myelodysplasia or AML.[76,77]

Myeloid progenitors from patients with CML in AP or BP have increased β-catenin levels compared with levels in control participants. Self-renewal of hematopoietic stem cells in mice entails activation of the β-catenin pathway, which results in the translocation of β-catenin to the nucleus, where it interacts with lymphoid enhancer factor/T-cell factor (LEF/TCF) transcription factors and regulates the transcription of genes such as *MYC* and *cyclin D1*.[78] It has been shown that progression to BP is associated with expansion of the myeloid

progenitor fraction, consisting mainly of granulocyte–macrophage progenitors, rather than expansion of the pool of hematopoietic stem cells. Of note, CML granulocyte–macrophage progenitors display *BCR-ABL1* amplification and activation of the β-catenin pathway, enhancing the self-renewal activity and leukemic potential of these cells.[79]

One of the most common gene mutations in CML-BP involves the *p53* gene, which is mutated in 25% to 30% of patients with myeloid BP, and the exon 2 of the *INK4A/ARF* locus, which is deleted in 50% of cases of lymphoid BP.[71] Deletion of exon 2 of the *INK4A/ARF* locus results in loss of *p16* and *p14/ARF* expression, which regulate cell cycle progression and the G_1/S checkpoint by inhibiting the G_1 phase cyclin D-Cdk4/Cdk6 and promoting p53 upregulation, respectively.[71] Based on the fact that ARF enhances p53 levels by interfering with the activity of MDM2, the principal negative regulator of p53,[80] homozygous deletion at the *p16/ARF* locus observed in lymphoid BP might represent a functional equivalent of *p53* mutation in myeloid BP.[71] Two other elements upregulated by BCR-ABL in CML-BP are the transcription factors encoded by *EVI-1* and *HOXA9,* which can cooperate with BCR-ABL in blocking myeloid differentiation and enhancing survival advantage.

Notably, BCR-ABL enhances SET expression during progression to BP.[81] SET is a nucleus/cytoplasm-localized phosphoprotein that potently inhibits the tumor suppressor protein phosphatase 2A (PP2A). In turn, PP2A is a phosphatase that regulates cell proliferation, survival, and differentiation.[82]

In summary, progression to CML-BP is characterized by a multitude of heterogenous cytogenetic and molecular alterations responsible for reduced apoptosis, enhanced proliferative potential, and differentiation arrest observed in CML-BP cells. A better understanding of these abnormalities, which will undoubtedly depend on the development of better animal models of advanced CML phase, is warranted to design rational therapies for patients in BP.

ACUTE MYELOID LEUKEMIA

Acute myeloid leukemia is a heterogeneous disease with regard to acquired genetic alterations, including cytogenetic aberrancies as well as gene mutations and changes in gene expression. Most cases of AML are sporadic and occur as a consequence of acquired somatic mutation in hematopoietic stem cells. Cytogenetic aberrations are detected in approximately 50% to 60% of patients with AML at the time of diagnosis and constitute the strongest predictor of clinical outcome.[83-86] However, there is significant variation in clinical outcome across different cytogenetic aberrations. In addition, there is enormous variability in prognosis within the same group of karyotypic alterations, indicating that other molecular events play a major role in the pathogenesis of AML. Identification of these abnormalities is needed to better understand AML, to improve the prognostic value of the cytogenetic analysis, and to better stratify patients with AML. In patients whose pretreatment karyotype is abnormal, cytogenetic analysis is customarily used to document complete remission after remission induction therapy. Multiple translocation breakpoints have been identified and cloned over the past decade from patients with AML. It is possible to classify these translocations based on the structure and function of the genes involved. Frequently, these balanced reciprocal translocations involve the fusion of two transcription factors important in normal hematopoiesis such as core binding factor (CBF), retinoic acid receptor alpha (RARa), homeobox (HOX) family members, and members of the ETS family of transcription factors. Of critical importance has been the discovery of mutations in several elements involved in survival, proliferation, and differentiation, such as the receptor tyrosine kinase receptors FMS-like tyrosine kinase 3 (FLT3), and KIT. The discovery of these mutations has added significant complexity to the pathogenesis of AML but also helped to better classify, stratify, and prognosticate different subsets of patients with AML. Moreover, this has unveiled novel targets that have spurred the development of experimental agents for this disease. Recent progress in deep-sequencing has facilitated genome-wide analysis of AML. Numerous new mutations have been reported that require further analysis regarding their roles as "driver" or "bystander" mutations.

Prognosis Based on Cytogenetic Analysis

Acquired structural chromosome aberrancies are detected at diagnosis in the BM of 50% to 60% of patients with AML .[83-85,87] Three distinct risk groups—favorable, intermediate, and adverse—can be established based on karyotypic findings. All large cytogenetic studies of AML concur that patients with t(15;17)(q22;q12-21) have an excellent prognosis and those with t(8;21)(q22;q22) or inv(16)(p13q22)/t(16;16)(p13;q22) have a relatively favorable prognosis. By contrast, patients with inv(3)(q21q26)/ t(3;3)(q21;q26), -7 or a complex karyotype (i.e., at least three chromosome aberrations) have a poor clinical outcome. The presence of the poor risk cytogenetic abnormalities -5, del(7q), -17/17p-, -18, or -20 is frequently associated with complex karyotypes.[87] Most large studies evaluating the prognosis of karyotypic abnormalities in AML have been undertaken in patients younger than 60 years of age.[83-85] The value of the pretreatment cytogenetic analysis has been recently corroborated in trials involving older patients with AML.[88,89] In these studies, the longest survival was observed in patients with CBF AML.[88,89] Patients with normal karyotype at diagnosis are classified in the intermediate prognostic category.[83-85] However, the prognosis within this subset of patients is highly variable, likely because of the presence of a heterogeneous group of molecular alterations undetectable by standard karyotypic analysis. A flurry of recent studies has highlighted the prognostic importance of different molecular markers in patients with normal karyotype (e.g., *NPM1, FLT3,* and *KIT* mutations). The complex interactions among these molecular abnormalities have not been elucidated yet.

Pathogenesis

In AML, the enormous complexity and diversity of genetic and molecular genotypes exceeds the number of recognizable clinical and morphologic phenotypes. A working formulation that rationally categorizes the wealth of available genetic and emerging molecular information is therefore necessary. A currently accepted notion of AML pathogenesis involves the cooperation of two different types of genetic abnormalities or mutations. The most frequently mutated genes in AML encode transcription factors, thus emphasizing the critical role of these "master" regulators in the control of hematopoietic cell development. Translocations that inappropriately activate transcription factor genes display specificity for hematopoietic cells blocked in defined stages of differentiation. A direct consequence of these mutations is the impairment of the processes of maturation and differentiation of cells of the myeloid lineage. A second type of mutations is those that confer a proliferative and survival advantage to cells (activating mutations).[90] An example of the former include the CBF translocations and RARα and MLL gene rearrangements. Examples of the latter include mutations in receptor tyrosine kinases such as KIT or the FLT3 genes.[90] Some of the mutations conferring proliferative and survival advantage correlate with karyotypic aberrations observed in patients with AML at diagnosis.

Mutations Interfering With Transcription in Acute Myeloid Leukemia

Two distinct groups of transcriptionally active proteins play a major role in the fate of hematopoietic progenitors. The first group consists of master regulatory transcription factors, which, similar to AML1, are implicated in the development of all the hematopoietic lineages. Disruption of the signaling stemming from this type of proteins results in complete failure of the hematopoietic program. A second category of transcription factors intervenes more specifically in the

development and each hematopoietic lineage. Examples of this type of transcription factors are GATA-1, which skews the development of hematopoietic progenitors toward the erythroid lineage, and C/EBPα, which promotes granulocytic differentiation. The activity of some transcription factors depends on the cell type in which they are expressed. For instance, PU.1 induces B-lymphoid or myeloid differentiation (depending on its expression levels) when expressed in early hematopoietic progenitors, but it induces monocytic differentiation when expressed in committed myeloid precursors. Mutations and rearrangements of some transcription factors regulate the activity of different elements involved in signal transduction networks and of other transcription factors implicated in leukemogenesis. To identify the critical pathways responsible for AML pathogenesis, it is imperative to decipher with accuracy the cross-talk among the different classes of transcription factors and their mutated counterparts.

Core Binding Factor Rearrangements

Mutations involving CBF rearrangements are detectable in approximately 15% of patients with AML and are generally linked to a favorable prognosis. CBF is a heterodimeric transcription factor that consists of a DNA binding α-subunit, encoded by one of three members of the RUNX family (*RUNX1 or AML1, RUNX2,* and *RUNX3*), and a ß-subunit encoded by the *CBFβ* gene that increases DNA-binding affinity to the complex. CBF regulates the expression of an array of genes that modulate hematopoiesis, such as IL-3, GM-CSF, and the macrophage colony-stimulating factor (M-CSF) receptor. The CBFβ–RUNX3 complex is involved in B-cell maturation and the silencing of the *CD4* gene during T-cell maturation.[91] A *CBFα2* knock-out murine model renders a phenotype characterized by early embryonic death; central nervous system hemorrhage; and despite the presence of a normal yolk sac, absence of definitive hematopoiesis.[92,93] Rearrangements of *AML1* and *CBFβ* with other genes result in chimeric proteins that disrupt the CBF complex and represses transcription activation.[94] A variety of chromosomal translocations involving either *AML1* or *CBFβ* have been identified in AML. CBF AML include those expressing inv(16)/t(16;16), which gives rise to the fusion of *CBFβ* with the *smooth muscled myosin heavy chain* gene (MYH*11* or *SMMHC*), and t(8;21), which is associated with the fusion transcript composed of the *AML1* and the *eight-twenty-one (ETO)* genes. The AML1 gene has been found implicated in other fusion transcripts detected in AML, such as those involving the *ecotropic viral integration 1 (EVI1)* or *translocation ets leukemia (TEL)* genes in AML carrying the t(3;21) and t(12;21) translocations, respectively. Trisomy 13 has been shown to be strongly associated with AML1 mutations and FLT3 gene overexpression in AML.[95] Several types of *CBFβ-MYH11* transcripts have been described, depending on the fused exons of the *CBFβ* and *MYH11* genes, with almost 85% of cases presenting the transcript type A and 15% the transcripts D and E or other rarer isoforms.[96,97] In addition to the expression of these fusion oncoproteins, the normal unrearranged genes (e.g., *AML1*) continue to be expressed and both modulate the activity of each other. For instance, in AML expressing the CBF translocation *AML1-ETO,* this fusion oncogene acts as a dominant negative inhibitor of *AML1,* as evidenced in transcriptional activation assays[98] and knock-in murine models.[99] In fact, coexpression of *AML1-ETO* and *AML1* gives rise to an identical phenotype than that of embryos that completely lack *AML1*.[99] Similarly, the *CBFβ-MYH11* oncoprotein is a dominant negative inhibitor of CBF both in transactivation assays and during development.[100,101] Induction of *CBFβ-MYH11* expression or AML1-loss in BM does not appear to impair the maintenance of long-term hematopoietic stem cells. In knock-in *CBFβ-MYH11* chimeras, *CBFβ-MYH11* expression alters adult multilineage hematopoietic differentiation.[102] The multistep nature of leukemia progression in inv(16) AML expressing *CBFβ-MYH11* was also corroborated in these murine model in which gain of additional mutations induced by chemical or retroviral mutagens was necessary for the development of AML.[102,103] Interestingly, this phenotype was rescued in *CBFβ*$^{-/-}$ mice expressing *CBFβ* from the hematopoietic specific promoters *TIE2* or *GATA1,* further underscoring the key role of *CBFß* during hematopoietic differentiation.[104,105] *CBFß* also modulates the effect of *CBFβ-SMMHC* in adult hematopoiesis and leukemogenesis. In mice with a *CBFβ* knock-out allele and a conditional *CBFβ MYH11* knock-in allele, *CBFβ* modulated *CBFβ MYH11*–mediated leukemia development, suggesting that *CBFß* upregulation may efficiently counteract differentiation defects in human AML with inv(16).[106] In a conditional *CBFβ MYH11* knock-in mouse model, Cre-mediated induction of *CBFβ MYH11* in adult mice resulted in a drastic reduction in the numbers of B cells and platelets and the development of an abnormal myeloid progenitor population with deficient proliferation capacity in BM.[107] This study provides evidence in vivo that leukemia fusion proteins that affect hematopoietic differentiation may maintain normal number of hematopoietic stem cells with deficient repopulation function while creating preleukemic myeloid progenitors that can be targets for AML transformation.[107]

In summary, genetic rearrangements of CBF are frequent in patients with AML and usually occur through balanced reciprocal translocations, accounting for approximately 25% of cases of all cases of AML. Patients with CBF AML have a relatively favorable prognosis, which can be improved by postremission therapy with high-dose cytarabine.[108]

PML-RARα Rearrangements

Translocations involving the *retinoic acid receptor (RAR)* locus on chromosome 17, such as t(15;17)(q22;q11), are linked to the phenotype of acute promyelocytic leukemia (APL),[109-114] which comprises 10% to 15% of all cases of adult AML. The t(15;17)(q22;q11) gives rise to the *PML-RARα* transcript that encodes a fusion protein containing most of the functional domains of RARα (including the *RAR* binding domain and the DNA binding domain) and the majority of the *PML* gene. The breakpoints within the PML gene cluster locate to three different regions referred to as bcr1, bcr2, and bcr3.[115]

In addition to t(15;17)(q22;q11), there are at least two other variant translocations involving *RARα* associated with the APL phenotype. These include t(11;17)(q23;q21) and t(5;17)(q35;q21), which lead to the fusion of the *RARα* gene to the promyelocytic leukemia zinc finger *(PLZF)* and nucleophosmin *(NPM)* genes, respectively.[116] Other genes, such as *NuMA* and *STAT5,* have been found as much rarer *PML* translocation partners. The leukemogenic effect of *PML-RARα* has been demonstrated in transgenic models.[117,118] In these models, the development of APL occurred after a long preleukemic phase characterized by myeloproliferation, suggesting that additional genetic events are necessary for leukemogenesis. In fact, recurring, nonrandom cytogenetic abnormalities have been identified in PML-RARα transgenic mice that progress to APL.[119-121] Oncogenic *RAS* mutations have been identified in 10% to 15% of patients with AML,[122,123] suggesting a likely role as cooperating second hits in leukemogenesis. Oncogenic *N-RAS* and *K-RAS* mutations have been detected in 4% to 10% of patients with APL in two large studies.[123,124] It has been shown that conditional expression of oncogenic *K-RAS* from its endogenous promoter cooperates with *PML-RARα* in mice to induce a rapid-onset high-penetrance lethal APL-like disease.[125]

Transgenic mice expressing *PML-RARα, NPM/RARα,* or *PLZF/RARα* under the control of a human *cathepsin G* minigene have been recently generated.[126] In all three transgenic models, leukemia developed with variable penetrance after a variably long latency. Notably, distinct cytomorphologic features were induced by each fusion gene, with *hCG-NPM/RARα* leukemic cells resembling monoblasts, those expressing *hCG-PML/RARα* resembling promyelocytic blasts, and those expressing *hCG-PLZF/RARα* displaying a phenotype of terminally differentiated myeloid cells.[126] The PML-RARα oncoprotein disrupts the interaction of retinoic acid and *RARα*, which converts the latter into a transcription activator.[127] As a consequence, in APL, there is maturation arrest of hematopoietic progenitors at the promyelocyte stage. *PML-RARα* expression also disrupts the localization of native PML, causing it to relocalize from discrete nuclear structures,

the PML nuclear bodies, into microspeckled aberrant structures.[128,129] Similar to CBF fusion proteins, the PML-RARα oncoprotein is considered to act as a dominant negative inhibitor of the PML protein, as well as the major heterodimeric partner of RARα, RXRα (retinoid X receptor).[128] PML-RARα recruits and complexes with several corepressors, including the nuclear corepressor (N-CoR). N-CoR inhibits transactivation from RARα target genes through the recruitment of the molecules sin3 and histone deacetylases, which in turn inhibit the binding of transcription factors and the binding of the transcriptional machinery to promoters, resulting in inhibition of gene expression for hematopoietic differentiation. Similarly, the PML moiety of the PML-RARα protein interacts with the DAXX corepressor. Mutations preventing DAXX recruitment, albeit allowing PML-RARα dimerization, abrogated the ability of PML-RARα to block hematopoietic differentiation and immortalize cells.[130]

All-trans retinoic acid (ATRA) is the mainstay of the treatment for patients with APL, inducing leukemic cell differentiation and remission in patients with t(15;17)/*PML-RARα* or t(5;17)/*NPM-RARα*.[131] Similarly, arsenic trioxide (As_2O_3) has been demonstrated to be effective in the treatment of de novo as well as of ATRA-resistant t(15;17)/*PML-RARα* APL.[132] Current evidence suggests that the combination of ATRA and As_2O_3 may represent an alternative to chemotherapy for the treatment of APL expressing *PML-RARα*.[133] Comparison of gene expression profiles set by *PML-RARα* and *PLZF-RARα* in the absence of ATRA therapy has demonstrated the inhibition of genes involved in DNA repair, repression of myeloid transcriptional regulators, and activation of the WNT–catenin and Jagged–NOTCH pathways, which promote self-renewal of leukemic cells.[134] Interestingly, patients with APL harboring t(15;17)(q22;q11)/*PLZF-RARα* fail to respond to ATRA. Paradoxically, both *PML-RARα* and *PLZF-RARα* contain identical *RAR* sequences and inhibit ATRA-induced gene transcription as well as cell differentiation. Both fusion proteins recruit the nuclear corepressor N-CoR–histone deacetylase complex through the *RARα* CoR box. Although ATRA can induce dissociation of N-CoR from PML-RARα, it does not affect its association with the PLZF-RARα fusion protein, thus resulting in persistent block in gene expression and hematopoietic differentiation.[135] This insensitivity is mediated by the N-terminal PLZF moiety of the chimera. Not surprisingly, histone deacetylase inhibitors antagonize the oncogenic activities of the PML-RARα fusion protein and partially relieve the transcriptional repression by PLZF and the inhibitory effect of PLZF-RARα on ATRA response.[117,135,136] Whereas conditional expression of the PML-RARα protein suppressed the expression of the transcription factor *PU.1,* treatment of APL cell lines and primary leukemic cells with ATRA restored the expression of the transcription factor *PU.1* and induced neutrophil differentiation.[137]

MLL Gene Rearrangements

Mixed-lineage leukemia (MLL), also known as ALL-1, HRX, or HTRX1, is the human homolog of Drosophila TRX and constitutes a maintenance factor for the homeobox (HOX) group of proteins, which are central to cell fate during development and hematopoiesis.[138] The N-terminus of *MLL,* which contains the AT-hook DNA-binding motif and a region homologous to DNA methyltransferase, is always retained in the fusion protein, but the C-terminus, which contains the activation and SET domains, is always replaced by the fusion partner.[139] The *MLL* AT hooks bind to the minor groove of DNA, which facilitates the binding and recruitment of transcription factors to enhancer and promoter elements.[140] This might explain the HOX gene upregulation and transformation detected in leukemia-associated MLL gene rearrangements.

MLL fusion genes can initiate both myeloid and lymphoid leukemogenic programs in primary human hematopoietic cells depending on the identity of the fusion partner, as well as by microenvironmental signals.[141] Most translocation junctions cluster within the 8.3-kb *breakpoint cluster region* (bcr) of the *MLL* gene at chromosome band 11q23.[142] Approximately 4% of patients with de novo AML have balanced translocations or insertions involving the *MLL* gene. *MLL* gene fusions are highly associated with previous therapy with topoisomerase II inhibitors such as etoposide and with the monocytic FAB-subtype M5a. The estimated incidence of this type of rearrangements in secondary treatment-related AML is 2% to 12%.

Similar to other genes involved in the pathogenesis of AML, *MLL* is critical both in embryonic development and in hematopoiesis. Mice lacking the *MLL* gene perish very early during embryonic development,[143,144] and $MLL^{(+/-)}$ mice display defects in hematopoiesis, including anemia. In AML, more than 65 different chromosomal regions have been thus far identified as *MLL* fusion partners.[145] All *MLL* rearrangements contain invariably a truncated MLL gene product expressed from its own promoter. For instance, the *MLL-AF9* fusion transcript gives rise to AML when knocked in to the *MLL* locus,[146,147] and *MLL-AF4* can transform primary hematopoietic cells.[148] In addition, some patients with AML present with rearrangements of *MLL* in which *MLL* is not fused with a partner gene but rather is elongated by means of an in-frame partial tandem duplication (*MLL*-PTD) of exons 11-5 or 12-5.[149] *MLL*-PTD occur chiefly in normal karyotype AML or in trisomy 11 and can be identified in 5% to 10% of all AML cases. Approximately 4% to 7% of patients with AML with normal cytogenetics carry *MLL*-PTD, which confers an especially poor prognosis.[150] It has been recently shown that *MLL*-PTD is associated with increased histone H3/H4 acetylation and methylation of H3 Lys4 at *cis*-regulatory *HOXA* sequences, indicating that *MLL* gene rearrangement can directly alter *HOXA* gene expression.[151] AML associated with *MLL* gene rearrangements portends an unfavorable prognosis.

Rearrangements Involving *HOX* Genes

HOX genes are frequently overexpressed in leukemia.[152] Expression of *HOX* genes is tightly regulated during hematopoietic ontogeny. *HOX* genes are expressed in early hematopoietic progenitors but are undetectable in terminally differentiated cells. Gene expression profiling analysis showed that the *HOXA4, HOXA9, HOXA10, PBX3,* and *MEIS1* homeobox genes are coexpressed across diverse cytogenetic groups, suggesting a coregulated pathway with pathogenetic relevance in a subgroup of AML.[153] Deregulation of *HOX* genes occurs in AML by different mechanisms. *HOX* genes are mainly disrupted via chromosomal translocation. For instance, *HOXA9* and *HOXD13* are deregulated through the t(7;11) and t(2;11) translocations, respectively,[154] giving rise to fusion proteins between the HOX protein and the nucleoporin 98 kDa (NUP98) nuclear protein. The NUP98 moiety of HOXA9-NUP98 has transactivating capacity and interacts with the transcriptional coactivator *creb binding protein (CBP)/p300.*[140] HOXA9-NUP98 is predominantly localized to the non-nucleolar portion of the nucleus rather than to the nuclear membrane, which seems to indicate that nucleoporin fusion genes might affect transport of mRNA through the nuclear membrane.[140] Other nucleoporing-containing fusion genes have identified *NUP98* and *NUP214* (also known as *CAN*) fused to *HOXA9, HOXD13, DEK,* and the putative RNA helicase *DDX10.*[140] Overexpression of *HOXA6, HOXA7, HOXA9,* and the HOX cofactor *myeloid ecotropic viral integration site 1 (MEIS1)* has also been correlated with chromosome 11q23 abnormalities involving the MLL protein, which directly regulates the expression of *HOX* genes.[155] The *caudal-type homeobox transcription factor 2 (CDX2),* a *HOX* gene involved in anteroposterior axis definition and intestinal epithelial cell differentiation,[156] is overexpressed in 90% of patients with AML despite its lack of expression in hematopoietic progenitors.[157] *CDX2* overexpression in primary murine hematopoietic progenitors resulted in transplantable AML in vivo, coinciding with a threefold upregulation in *HOXB6* expression,[157] a protein that is overexpressed in 40% of cases of AML with a normal karyotype.[158] This suggests the possibility that *CDX2*-mediated deregulation of *HOX* genes is a major pathway to leukemogenesis. Supporting this hypothesis is the fact that *CDX4* expression is deregulated in 25% of cases of AML.[159]

Mutations in the *C/EBPα* Gene

The *C/EBPα* gene, which encodes the CCAAT/enhancer-binding-protein-α, is a member of the family of leucine zipper (bZIP) transcription factors that couples lineage commitment to terminal differentiation and cell cycle arrest in the process of myeloid differentiation.[160] *C/EBPα* plays a crucial role in regulating the balance between cell proliferation and differentiation.[161,162] It initiates growth arrest through induction of *p21* and by disrupting the E2F transcriptional complexes during the G1 phase of the cell cycle.[163,164] Mutations in the *C/EBPα* gene occur in 15% to 19% of patients with AML and normal cytogenetics.[165-167] The latter consist of either in-frame C-terminal mutations in the bZIP domain that mediates DNA binding and homo- and heterodimerization with other CEBP proteins or N-terminal nonsense mutations that result in premature termination of the *C/EBPα* protein and lead to complete loss of *C/EPBα* function owing to the dominant negative inhibition of wild type *C/EBPα*–DNA binding and transactivation.[160] *C/EBPα* mutations increase the capacity of BM myeloid progenitors to proliferate and predispose mice to a granulocytic myeloproliferative disorder and transformation of the myeloid compartment of the BM.[165] It has been shown that *FLT3* mutations in human AML inhibit the function of *C/EBPα* by ERK1/2-mediated phosphorylation, which may explain the differentiation block of leukemic blasts.[168] Patients harboring *C/EBPα* mutations present with higher percentages of peripheral blood blasts, lower platelet counts, and less frequent extramedullary involvement and are less likely to carry the deleterious *FLT3* and *MLL-PTD* mutations.[166] In the absence of specific *C/EBPα* mutations, decreased expression may serve as an alternative mechanism that disrupts *C/EBPα* gene function. For example, *AML1-ETO* appears to indirectly suppress *C/EBPα* expression by inhibiting positive autoregulation of the *C/EBPα* promoter.[169] In fact, patients with AML and t(8;21) have up to sixfold less *C/EBPα* mRNA than patients with AML and a normal karyotype.[169] Conditional expression of *C/EBPα* in *AML1-ETO*-positive AML cell lines results in neutrophilic differentiation.[169] Importantly, *C/EBPα* mutations have been shown to be associated with a favorable prognosis in patients in the cytogenetic intermediate-risk category and may improve risk stratification in patients with normal cytogenetics.[166,167]

Mutations in the *PU.1* Gene

The transcription factor PU.1 encoded by the *Sfpi1* (spleen focus-forming virus proviral integration) gene is indispensable for myelomonocytic differentiation during normal hematopoiesis[170] and for regulating the commitment of multipotent hematopoietic progenitors.[171] Aberrant levels of expression of PU.1 are leukemogenic. Transcriptional control of *Sfpi1* gene expression is regulated by a distal upstream regulatory element (URE) that is highly conserved.[172] Knock-out of URE reduces expression of *PU.1* by 80% in the BM and leads to the development of AML in mice.[173] This suggests that reduced PU.1 levels are sufficient to support the survival of myeloid progenitors but not to sustain their differentiation, possibly because of deregulation of the expression of some cytokine receptors.[173] Interestingly, the course of AML in mice after knockdown of *PU.1* includes a preleukemic stage during which immature myelomonocytic precursors accumulate in the BM followed by a leukemic phase with elevated leukemic blasts in peripheral blood.[173] Repressed *PU.1* transcription has been reported in AML expressing *PML-RARα*[137] or internal tandem duplication *FLT3 (FLT3-ITD)* mutations,[174] and *AML1-ETO* functionally inactivates PU.1 by displacing its coactivator JUN. By means of genome-wide transcriptional analysis of hematopoietic stem cells isolated from mice in which *PU.1* was knocked down at the preleukemic stage, it has been shown that the transcription factors *c-JUN* and *JUNB* were among the top-downregulated targets.[175] Restoration of *c-JUN* expression in preleukemic cells rescued the *PU.1* knockdown-initiated myelomonocytic differentiation block, but restoration of *JUNB* led to loss of leukemic self-renewal capacity and abrogated the development of AML in NOD/SCID (nonobese nondiabetic/severe combined immune deficient) mice transplanted with leukemic *PU.1*-knockdown cells.[175] Despite of the evident leukemogenic potential of deregulated *PU.1*, mutations in this transcription factor have been rarely found in human AML.[176-178]

Mutations Altering Signal Transduction

Mutations of the Fms-Related Tyrosine Kinase 3 Gene

The *FLT3* gene locates to chromosome band 13q12 and encodes a membrane-bound structurally related to other class III tyrosine kinase receptors such as KIT, FMS, and platelet-derived growth factor receptor (PDGFR).[179] In the BM, FLT3 expression is restricted to $CD34^+$ cells and a subset of dendritic precursors, where it regulates proliferation, differentiation, and apoptosis of hematopoietic cell progenitors.[179] A series of models has investigated the role of FLT3 signaling in leukemogenesis. Retroviral transfection of primary murine BM cells with mutant *FLT3* fails to cause leukemia in mice but results in an oligoclonal fatal myeloproliferative disease after a latency period.[180,181] Internal tandem duplication (ITD) of the *FLT3* gene, occurring within the *FLT3* juxtamembrane domain (exons 14 and 15), is among the most prevalent mutations detected in patients with AML and normal karyotype, being detected in about 30% of cases.[182-184] Moreover, 7% of patients with AML harbor missense point mutations affecting the activation loop of the tyrosine kinase domain of FLT3 coded by exon 20.[182-184] A variety of kinase domain mutations have been reported. Most are point mutations such as substitution of aspartate residue 835 with a tyrosine (D835Y, which is the most frequent mutation), histidine, valine, or glutamate. Alternatively, other mutations include small deletions (Δ835, Δ836) and insertions. Evidence suggests that *FLT3* mutations occur in leukemic stem cells. In fact, 84% of patients with AML carrying *FLT3-ITD* mutations exhibit the same mutation at relapse.[185] Both *FLT3-ITD* and *FLT3* kinase domain mutations give rise to a constitutively active FLT3 protein that promotes ligand-independent proliferation and survival of leukemic cells.[184] Oncogenic activation of *FLT3-ITD* mutations activates aberrant signaling, including STAT5, and repression of myeloid transcription factors such as *PU.1* and *C/EBPα*.[186] In addition to STAT5, FLT3 signals through the PI3K/AKT and the mitogen-activated protein kinase (MAPK) pathways.[187] Interestingly, *FLT3-ITD* mutations collaborate with *AML1-ETO* in inducing acute leukemia in a murine BM transplantation model.[188] Patients carrying *FLT3* gene mutations have been largely associated with worse prognosis than those carrying wild type *FLT3*.[182,187,189,190] Small-molecule TKIs directed against the constitutively activated FLT3 protein such as PKC412,[191] lestaurtinib,[192] sorafenib,[193] or tandutinib[194] have shown encouraging results in early clinical trials, although complete responses have been rarely achieved. Further development of these agents must be pursued in combinatorial approaches including standard chemotherapy.

Mutations of the *KIT* Gene

The *KIT* gene, located at chromosome band 4q11-12, encodes a 145-kDa transmembrane receptor tyrosine kinase of the type III subgroup.[195] Structurally, the KIT protein is characterized by five immunoglobulin-like domains in the extracellular portion of the receptor, a transmembrane and juxtamembrane domains, and an intracellular kinase domain.[195] KIT is expressed in hematopoietic stem cells as well as in mast cells, germ cells, melanocytes, and interstitial cells of Cajal, among others.[195] Upon binding of the ligand stem cell factor (SCF) to the extracellular immunoglobulin-like domains, KIT undergoes homodimerization and autophosphorylation at the Y568 and Y570 tyrosine residues of the juxtamembrane domain, which activates downstream signaling pathways involved in proliferation, differentiation, and survival.[195] Gain-of-function point mutations in the kinase domain of KIT result in ligand-independent constitutive

activation of KIT signaling, which leads to uncontrolled cell proliferation and resistance to apoptosis.[196] Activation of the KIT tyrosine kinase by somatic mutation has been documented in a variety of human malignancies, including CBF AML, systemic mastocytosis, and gastrointestinal stromal tumors.[197-199] In AML, most *KIT* mutations cluster within exon 17, which encodes the KIT activation loop (A-loop) in the kinase domain, and in exon 8,[197,200-203] which encodes a highly conserved region in the extracellular portion of the KIT receptor, which is believed to play a role in receptor dimerization.[204] Interestingly, *KIT* mutations at exon 17 in patients with inv(16) occur exclusively at codon D816,[197,201] but in patients with t(8;21), they map primarily to codons D816 or N822.[197] *KIT* mutations confer a higher risk of relapse in patients with CBF AML.[197] Akin to other mutations of genes encoding tyrosine kinases in AML, such as *FLT3 ITD,* gain-of-function *KIT* mutations may serve as a target for TKIs. Indeed, variable responses to imatinib administered both as single-agent or in combination with other chemotherapeutics have been reported in CBF AML with *KIT* mutations at exon 8, but patients with *KIT D816* mutations did not show any response.[205] In vitro studies have shown that *KIT D816* mutations can be effectively targeted with TKIs such as PKC412[206] or dasatinib.[207] The activity of these agents warrants further investigation in clinical trials of patients with CBF AML harboring *KIT* mutations.

Mutations of the *RAS* Gene

RAS oncogenes encode a family of membrane-associated proteins that regulate signal transduction by binding to a variety of membrane receptors. In so doing, RAS proteins play important roles in the regulatory processes of proliferation, differentiation, and apoptosis. Abnormalities in *RAS* genes have been implicated in the pathogenesis of AML.[208] Mutations in all *RAS* gene homologs, *NRAS, KRAS,* and *HRAS,* take place at codons 12, 13, and 61. All RAS proteins possess a consensus guanosine triphosphate (GTP) binding motif that critical for intracellular signaling.[209] The RAS proteins oscillate between a GTP- and a guanosine diphosphate (GDP)–bound state. GDP-bound RAS is incapable of activating signal transduction pathways.[209,210] *NRAS* mutations appear to be the most frequent *RAS* mutations in patients with AML, being detected in 10% to 30% of patients.[122,208,209,211] Mutated RAS proteins are constitutively activated, which is held in their GTP-bound status. *NRAS* rapidly and efficiently induced an AML-like disorder in a mouse BM transduction and transplantation model, indicating that mutated *NRAS* can function as an initiating oncogene in the induction of myeloid malignancies.[212] Despite the potential implication of *NRAS* mutations in AML pathogenesis, their prognostic impact in AML remains controversial, with some studies associating the presence of these mutations with a poor prognosis[213,214]; others suggesting a favorable prognosis[215]; and some others in which the prognostic impact of *NRAS* mutations was neutral for overall survival, event-free survival, or disease-free survival.[122,123,211]

RAS may represent a potential therapeutic target in AML. Farnesyl transferase inhibitors (FTIs) constitute a class of drugs that targets the farnesylation of RAS proteins (required for the attachment of this protein to the plasma membrane).[216] This posttranslational modification is critical for RAS-mediated cell transformation.[217] However, the nonpeptidomimetic FTI tipifarnib used in combination with standard idarubicin and cytarabine induction chemotherapy has not improved the results compared with historical control participants in a recently reported study.[218]

Other Genetic Events Implicated in the Pathogenesis of Acute Myeloid Leukemia

Mutations of the Nucleophosmin Gene

The *nucleophosmin member 1 (NPM1)* gene located at chromosome band 5q35, encodes a nucleus-cytoplasm shuttling protein implicated in preventing nucleolar protein aggregation, regulation of ribosomal protein assembly, initiation of centrosome duplication, and regulation of the oncosuppressors *p53* and *p19ARF* and their partners (i.e., HDM2/MDM2).[219,220] The mechanisms whereby *NPM1* is involved in leukemogenesis have not been elucidated yet. *NPM1* is involved in control of primitive hematopoiesis, and *NPM1* is haploinsufficient for the control of proper centrosome duplication, resulting in genomic instability that results in a syndrome reminiscent of human myelodysplasia. The NPM1 protein regulates the ARF-p53 tumor-suppressor pathway.[221] Translocations involving the *NPM* gene cause cytoplasmic dislocation of the NPM protein. Mutations of *NPM1* result in the shift of the NPM1 protein into the cytoplasm and constitute the most frequent genetic aberration found in AML with normal karyotype.[220,221] Given that NPM1 is thought to have a tumor-suppressor function, alterations in its subcellular localization from the nucleus to the cytoplasm may be crucial for malignant transformation.[221] *NPM1* mutations are found in approximately 35% of adult patients with primary AML (excluding PML) and have been linked to a higher complete remission rate after induction chemotherapy.[221] Most of the cases (60%-80%) carrying a mutant *NPM1* gene correspond to patients with AML and normal karyotype.[221] A polymorphism of nucleotide T deletion at position 1146 in the *NPM1* 3′-untranslated region has been reported in 60% to 70% of patients with AML and in healthy volunteers.[222,223] *NPM1* mutations are typically heterozygous, and except for anecdotal cases involving the splicing donor site of *NPM1* exon 9 and exon 11, most mutations are restricted to exon 12.[221,224,225] The most common *NPM1* mutation is a duplication of a TCTG tetranucleotide at position 956 to 959 and accounts for 75% to 80% of cases.[220,225] Interestingly, *FLT3-ITD* mutations were seen twice as often in patients with mutated *NPM1* as in cases with wild type *NPM1,* suggesting a possible mechanistic link between *FLT3* and *NPM1* mutations.[220-222] Because immunohistochemical detection of cytoplasmic *NPM1* is predictive of *NPM1* mutations in AML[226] and these are associated with a better prognosis, the detection of NPM1 mutations may represent a valuable tool both for outcome prediction as well as for monitoring of minimal residual disease. Although NPM1 represents an attractive therapeutic target, the pharmacologic inhibition of this protein might be difficult given the fact that *NPM1* can function both as an oncogene and a tumor-suppressor gene,[219] depending on gene dosage, expression levels, interacting partners, and compartmentalization. In fact, partial functional loss and aberrant overexpression of *NPM1* both lead, through separate mechanisms, to abnormal cell growth.[219,220] The development of adequate experimental animal models of *NPM1*-positive AML will be critical to further ascertain the role of *NPM1* in the pathogenesis of AML and to test the efficacy of novel agents targeting NPM1.

Overexpression of the *BAALC* and *ERG* Genes

High expression of the brain and acute leukemia, cytoplasmic *(BAALC)* gene can be found in some patients with AML. Overexpression of *BAALC* mRNA in peripheral blood blasts has been shown to portend an adverse clinical outcome in patients younger than 60 years of age.[227] These have been confirmed in several independent studies. In one study, 307 patients younger than 60 years of age with AML and normal karyotype were analyzed.[190] BAALC overexpression predicted for failure to achieve complete response, primary resistant disease, and a remarkably shorter overall survival.[190] Results of another study suggested that high *BAALC* expression may represent a prognostic marker that is particularly useful in AML with normal karyotype lacking *FLT3*-ITD and *C/EBPα* mutations.[167]

The v-ets erythroblastosis virus E26 oncogene homolog (avian) *(ERG)* gene maps to chromosome band 21q22 and is involved in regulating and promoting cell differentiation, proliferation, and tissue invasion.[228] In one study, 84 patients with AML and a normal karyotype were analyzed for *ERG* expression using real-time polymerase chain reaction.[229] Patients with the highest *ERG* expression levels had a worse cumulative incidence of relapse than those with low expression ($P < .001$). Whereas in patients with low *ERG* expression, the

median survival had not been reached and the estimated 5-year survival was 51%, those with high *ERG* expression had an overall survival time of 1 to 2 years and an estimated 5-year rate survival of 19%. Interestingly, the adverse impact on overall survival conferred by high *ERG* expression was only observed in patients with low *BAALC* expression.[229]

In addition, mutations in IDH1 and IDH2,[230-232] ASXL1,[233] and DNMT 3A[234] have been reported.

Spliceosome Mutations

Alternatively spliced transcriptional isoforms are commonly found in the transcriptome of neoplastic cells, which often express specific transcripts that confer some survival advantage. But almost all genes are multi-exonic, and 95% of eukaryotic multi-exonic genes are alternatively spliced using the highly conserved splicing machinery that consists of small nuclear ribonucleoproteins (snRNPs) or associated protein factors. A spliceosome is a complex of snRNA and protein subunits that removes introns from a transcribed pre-mRNA (hnRNA) segment. Each spliceosome is composed of five small nuclear RNAs (snRNAs) and a range of associated protein factors. It catalyzes the removal of introns and the ligation of the flanking exons. Surprisingly, cancer-associated alternative splicing is not only the consequence of cis-acting DNA mutations in intron–exon boundary recognition sites, but recent next-generation sequencing projects have identified frequent somatic mutations in core splicing components in MDS[235,236] and secondary AML.[237] Eight different splicing component mutations have been identified (U2AF35, SF3B1, SRSF2, ZRSR2, SF3A1, PRP40B, SF1, and U2AF65); they are heterozygous and usually mutually exclusive.[235] Their overall frequency is 45% to 85%, and the most frequently abnormal gene, *SF3B1,* is mutated in up to 85% of refractory anemia with ring sideroblasts (RARS).[236] SRSF2 is mutated in 30% of CMML. Acquired mutations in these splicing factors are also found in chronic lymphocytic leukemia (9%-14%), myeloproliferative neoplasms, and de novo AML.[237,238] Interestingly, mutations in SF3B1 and DNMT3A, which encode a DNA methyltransferase, appear to co-associate.[238]

A recent report[239] of genome-wide analysis of alternative splicing in 81 AML and selected analysis in 193 AMLs found that alternative splicing is a common event involving many genes in any given patient. NOTCH2-Va (74 %), FLT3-Va (50 %), and CD13-Va (60 %) were the most frequently expressed variants in AML and NOTCH2-Va expression was negatively associated with overall survival ($P = .008$).

The molecular and biologic consequences of these mutations are not at all clear; early results are contradictory. Likewise, the potential of these splice variants as therapeutic targets has not yet been sufficiently explored.

FUTURE DIRECTIONS

Significant advances have been made over the past decades regarding the understanding of the mechanisms involved in the pathogenesis of myeloid leukemias. Most of this knowledge has been derived from the constant refinement of genetically engineered murine models of leukemia. These models have been particularly fruitful to demonstrate the multistep nature of the leukemogenic process based on the cooperation of a diversity of genetic abnormalities necessary for the development of human leukemias. A better understanding of the molecular underpinnings of myeloid leukemia has provided the opportunity to identify therapeutic targets. The development of targeted therapies against myeloid malignancies is epitomized by the remarkable success of the small-molecule kinase inhibitor imatinib mesylate in patients with CML. The main pathogenetic driver in CML can be ascribed to a single molecular defect, the BCR-ABL kinase. This has facilitated the development of a highly effective targeted agent such as imatinib, which constitutes the current standard for the treatment of CML. However, most patients receiving imatinib still harbor measurable amounts of residual leukemic cells, indicating that single-agent therapy with this TKI may not cure CML. It is likely that the complete eradication of leukemic cells in CML will be accomplished by using combinatorial approaches. In addition, a significant percentage of patients will develop mutations within the kinase domain of *ABL1* that will hinder the binding of imatinib and other small molecule inhibitors. Both nilotinib and dasatinib, second-generation ABL kinase inhibitors, have proven efficacious against most clinically relevant mutants, with the exception of T315I. Several agents, such as Aurora kinase inhibitors and JAK2, are currently under clinical development based on their in vitro activity against this mutation. Importantly, unlike patients with CML in CP, neither imatinib nor the potent second-generation TKIs nilotinib or dasatinib has proved effective in CML-BP, a condition that displays molecular features reminiscent of those of AML.

In AML, the discovery that mutation-induced deregulation of several tyrosine kinase receptors (e.g., KIT, FLT3) provides a survival and proliferative advantage to AML cells has opened the avenue of targeted therapies in this disease. The currently available agents directed against these kinases have produced short-lived responses. This is most likely because AML results from the alteration of multiple key elements in the homeostasis of the myeloid progenitors. A better understanding of the molecular pathways downstream of each of the oncogenes involved in the pathogenesis of AML will help extend the concept of targeted therapy of this disorder beyond the isolated paradigm that constitutes the success of ATRA therapy in patients with PML expressing *PML-RARα*. The efficacy of ATRA and arsenic trioxide in PML not only conveys the hope that therapy for other types of AML may diverge from the current practice of administration of cytotoxic agents but also underscores the therapeutic potential of targeting transcription factors for the treatment of AML. Translocation-generated oncogenic fusion proteins involving transcription factors are truly "tumor-specific" and as such provide novel targets for therapy. However, designing therapeutic modalities aimed at modulating transcription factors remains challenging. Several strategies deserve consideration, including (1) chimeric peptides that by binding both a transcription factor and a target DNA sequence can displace fusion oncoproteins away from proliferation-inducing genes,[240] (2) fusion proteins such as Tat-HoxB4 that allow entry of drugs into the cell nucleus to change the cellular phenotype,[241] and (3) reexpression of silenced genes by introducing large regulatory DNA sequences.[242] To further develop these strategies, it will be necessary to gain better insight of the early events of the leukemogenic process and into the biology of leukemia stem cells.

Finally, a mutagenic role of the very chemotherapy used to induce patients into remissions has been reported.[243] Hence, certain molecular changes observed at relapse may be induced by different antileukemic therapies, emphasizing the need for nongenotoxic therapies.[244,245]

CHAPTER 58

CLINICAL MANIFESTATIONS AND TREATMENT OF ACUTE MYELOID LEUKEMIA

Stefan Faderl and Hagop M. Kantarjian

Acute myeloid leukemia (AML) is a rare hematopoietic neoplasm of mainly older patients. About 12,000 persons are diagnosed with AML in the United States each year. Whereas the overall age-adjusted incidence rate is 3.4 per 100,000 persons, it is as low as less than 2 per 100,000 for people under 65 years to greater than 15 per 100,000 for those 65 years or older. About 9000 patients are expected to die each year with AML. Its high malignant potential, rapid progression, universally fatal outcome if left unattended to, and challenging clinical course continue to focus a high level of interest.

There has been a constant evolution of the understanding of many aspects of the biology of AML as it relates to blasts and their interactions with and interdependence on the microenvironment. Identification of molecular abnormalities has led to a reappraisal of the heterogeneity of AML.[1] That cytogenetic-molecular classifications have important practical implications and determine therapy is evident in the case of acute promyelocytic leukemia (APL), where differentiation therapy even in the absence of chemotherapy is highly effective. On the other hand, the so-called core binding factor (CBF) leukemias are exquisitely sensitive to cytarabine. Following identification of pathophysiologically relevant signaling pathways, numerous small molecules and other drugs are being developed for targeting these pathways. Despite recent progress, the essentials of AML therapy have not changed much in three decades and remain rooted in cytarabine/anthracycline combinations during induction followed by postremission therapy with either chemotherapy or stem cell transplant.[2] Challenges ahead include (1) identification of molecularly defined subgroups, (2) development of more powerful and specific targeted small-molecule inhibitors, (3) combination of new drugs with established treatments, and (4) definition of the best therapeutic approach for older patients.

PRESENTATION OF ACUTE MYELOID LEUKEMIA AT DIAGNOSIS

The signs and symptoms of AML mostly reflect the predominant cytopenias. With the exception of patients who have a history of an antecedent hematologic disorder such as a myelodysplastic syndrome (MDS), patients present with a short history (1 to 8 weeks) of constitutional complaints (fatigue, lack of energy, malaise, profuse sweats), manifestations of bleeding (such as from gums, bruising in the skin, epistaxis, menorrhagia), and fevers. Fevers should always be presumed to be secondary to infections even in the absence of an identifiable focus and lead to rapid institution of antibiotic therapy. "Tumor fever" is uncommon and remains a diagnosis of exclusion. Extramedullary infiltrations of leukemia cells in the gingiva, skin, lymph nodes, or other organs occur occasionally. Bone pains are infrequent even with excessive leukocytosis and should raise the suspicion of an acute lymphoblastic leukemia (ALL), especially in children. Likewise, signs and symptoms referable to central nervous system (CNS) involvement (cranial nerve defects and other focal neurologic abnormalities, mental status changes, seizure activity) are rare with the exception of AML with monocytic/monoblastic differentiation.

Given the nonspecific nature of the presenting symptoms, the physical examination elicits a variety of findings that in their aggregate can lead to a correct suspicion of the diagnosis of acute leukemia, but it is impossible to distinguish AML from ALL by the clinical presentation or examination findings alone. Patients may present with pallor, ecchymoses or petechiae, enlargement of lymph nodes, or rarely, hepatosplenomegaly. Examination of the lungs may reveal signs of symptoms of an infectious process. Some patients with AML will have no abnormal findings at physical examination.

The laboratory evaluation should include blood counts with evaluation of the blood smear, a standard chemistry panel (electrolytes, urea nitrogen, creatinine, total bilirubin, transaminases, uric acid, lactate dehydrogenase [LDH]), and coagulation studies, including prothrombin time (PT), partial thromboplastin time (PTT), and fibrinogen levels. Anemia and thrombocytopenia are universal. The white blood cell count (WBC) can vary from low to high but will range from 5000/μL to 100,000/μL in most patients. The highest WBC numbers are seen in myelomonocytic leukemias. A WBC exceeding 100,000/μL is considered an emergency, which requires immediate efforts to reduce the disease burden (e.g., leukapheresis, chemotherapy) because leukostasis may ensue in several vascular beds with potentially catastrophic consequences. However, there is not always a good correlation of the aggressiveness of the AML with the elevation of the WBC, and far lower WBC levels may elicit life-threatening symptoms. The WBC should therefore be assessed in the context of the patient's overall physical condition and other clinical and laboratory abnormalities (e.g., LDH, uric acid). Disseminated intravascular coagulation (DIC) is often seen in patients with myelomonocytic AML, APL, and any high-WBC AML in general. PT, PTT, and fibrinogen levels should be carefully followed. Subclinical DIC is common in other forms of AML as well. Abnormalities of renal and hepatic values may represent infiltration of these organs, even if subclinical.

Imaging studies are of little help in diagnosis but allow assessment of complications (pneumonia, cerebral bleed). At a minimum a chest x-ray examination is warranted. In view of findings of any neurologic deficit at presentation, the threshold for noncontrast computed tomography (CT) scan of the brain should be low. Further evaluations should be based on the clinical assessment of the patients.

CLASSIFICATION OF ACUTE MYELOID LEUKEMIA AND PROGNOSTIC FACTORS

The first systematic attempt to classify AML goes back to the French-American-British (FAB) group, which described subtypes mainly based on blast percentage, degree of differentiation, and on lineage involvement, which relied mainly on cytochemistry and then later on immunophenotype. The diagnostic algorithm now includes a morphologic assessment (including application of stains and cytochemical reactions), immunophenotyping by flow cytometry, and assessment of karyotype and molecular studies (Fig. 58-1).

Blast percentage is best determined on a 500-cell differential of the marrow aspirate. Three broad types of myeloblasts have been defined within the FAB classification and are essentially based on the granular content and nuclear features of the blasts (type 1: agranular basophilic cytoplasm, nucleus with fine chromatin and two to four distinct nucleoli; type 2: basophilic cytoplasm with 20 or fewer

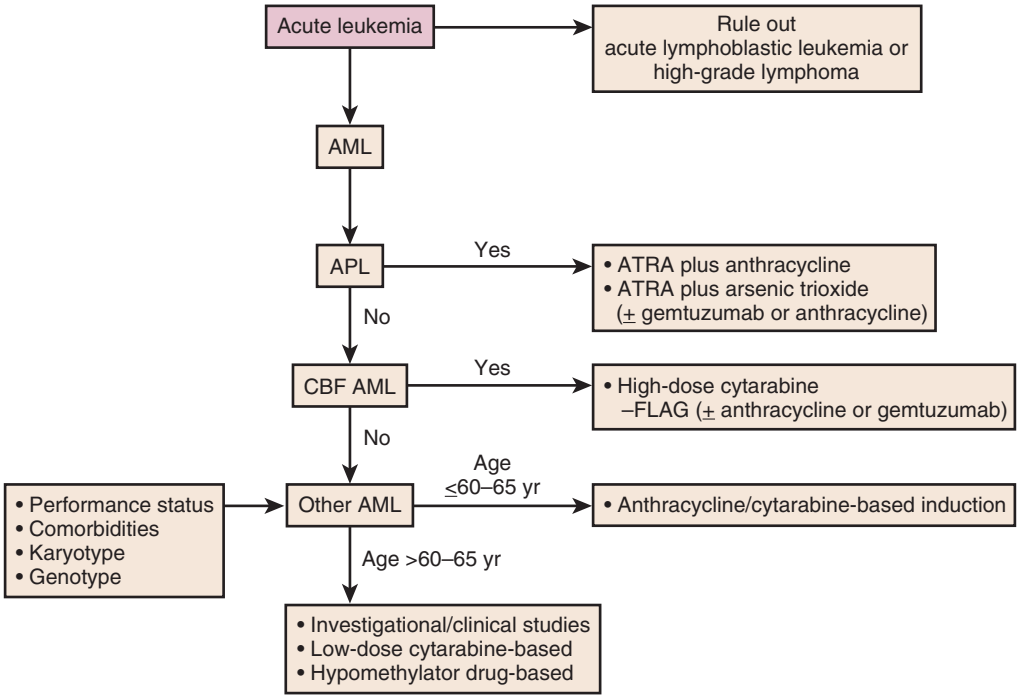

Figure 58-1 DIAGNOSTIC ALGORITHM OF ACUTE MYELOID LEUKEMIA (AML). The diagnostic workup consists of a morphologic assessment (including application of stains), immunophenotyping by flow cytometry, and assessment of the karyotype. Whereas morphologic assessment by itself is often not specific enough (including use of special stains), flow cytometry is nowadays always required to confirm the lineage assignment (myeloid versus lymphoid) and stage of differentiation. In more than 95% of cases, a lineage can thus be assigned to the blast phenotype. In only a few cases, no lineage-specific antigens are expressed (acute undifferentiated leukemia) or antigens of more than one lineage are present (mixed-phenotype acute leukemia). In the latter scenario, antigens of several lineages can be found on one blast population (biphenotypic) or several types of blasts, each expressing a more or less lineage-specific set of antigens (bilineal) can be detected. Karyotyping may add additional diagnostic information in some of those morphologically ambiguous situations but is far more useful prognostically in most other patients. The combined assessment applying the aforementioned methods, including information from the patient's prior history (exposure to previous chemotherapy agents and/or radiation therapy), forms the basis for the classification of AML, according to the World Health Organization system as per its most recent revision in 2008 (see Table 58-1). *MPO,* Myeloperoxidase; *WHO,* World Health Organization.

azurophilic granules and similar nuclear features as type 1 blasts; type 3: basophilic cytoplasm with more than 20 azurophilic granules), although the morphologic features of blasts are even more varied (Fig. 58-2). Promyelocytes have moderately basophilic cytoplasm with numerous azurophilic granules, and monoblasts and promonocytes usually exhibit folded/convoluted nuclei and may contain prominent acidophilic nucleoli. Promyelocytes, promonocytes, and atypical pronormoblasts may be considered as blast equivalents in some defined AML subgroups (APL, acute monoblastic leukemia, and acute erythroleukemia, pure erythroid type). Micromegakaryocytes and pronormoblasts are not considered blasts (see Fig. 58-2). Auer rods are rod-like filaments of aggregated primary granules that are found in 30% to 50% of newly diagnosed patients with AML and if present are one of the hallmark morphologic features to establish a diagnosis of AML (see Fig. 58-2, *C*) . AML marrows are typically hypercellular with decreased or absent megakaryocytes. Exceptions, however, exist. Samples of marrows of older patients or those with therapy-related AML may be hypocellular and include dysplastic changes of one or several blood lineages. Prominent dysplasia may suggest a previous diagnosis of MDS but can also be found in patients with de novo AML, where the prognostic significance of dysplastic changes is far less clear. Cases with extensive fibrosis may represent a preceding myeloproliferative disorder or acute megakaryocytic leukemia.

Several cytochemical reactions are in use to further highlight morphologic characteristics (myeloperoxidase [MPO], periodic acid–Schiff, Sudan black B, naphthol AS-D chloroacetate esterase [specific esterase], α-naphthyl acetate/butyrate esterases [nonspecific esterases], acid phosphatase) (Fig. 58-3). Among those, MPO is the most specific granulocytic marker, and the presence of MPO in at least 3% of the blasts is consistent with a diagnosis of AML. Absence of MPO staining does not rule out the possibility of AML because it is typically not present in AML with minimal differentiation, acute monoblastic leukemia, and acute megakaryocytic leukemia. Monoblastic leukemias are stained by nonspecific esterases. Whereas the MPO reaction is relatively uncomplicated and results are available quickly, this is not the case with most of the other cytochemical reactions, and their diagnostic utility is therefore often outdone by immunophenotyping by flow cytometry.

The limited scope of the FAB system became inadequate in view of rapidly growing information from cytogenetic-molecular abnormalities, their association with prognosis, and, in some cases, prediction of response to therapy. Although the hallmark of the diagnostic workup of AML remains a thorough assessment of Wright or Wright-Giemsa–stained blood and marrow smears, cytochemistry, and evaluation of the immunophenotype, cytogenetic-molecular markers are rapidly becoming the defining features of AML subtypes. The most recent World Health Organization (WHO) classification of AML primarily incorporates karyotype and genetic abnormalities together with morphologic descriptions related to dysplasia-related changes and remnants of the FAB system and information regarding exposure to prior chemotherapy and/or radiation therapy (Table 58-1).

The 2008 WHO classification divides AML into a number of broad categories. The first is AML with recurrent genetic abnormalities. This includes AML with relatively common genetic and cytogenetic changes: AML with t(8;21)(q22;q22), RUNX1-RUNX1T1 (Fig. 58-4); AML with inv(16)(p13.1q22) or t(16;16)(p13.1;q22),

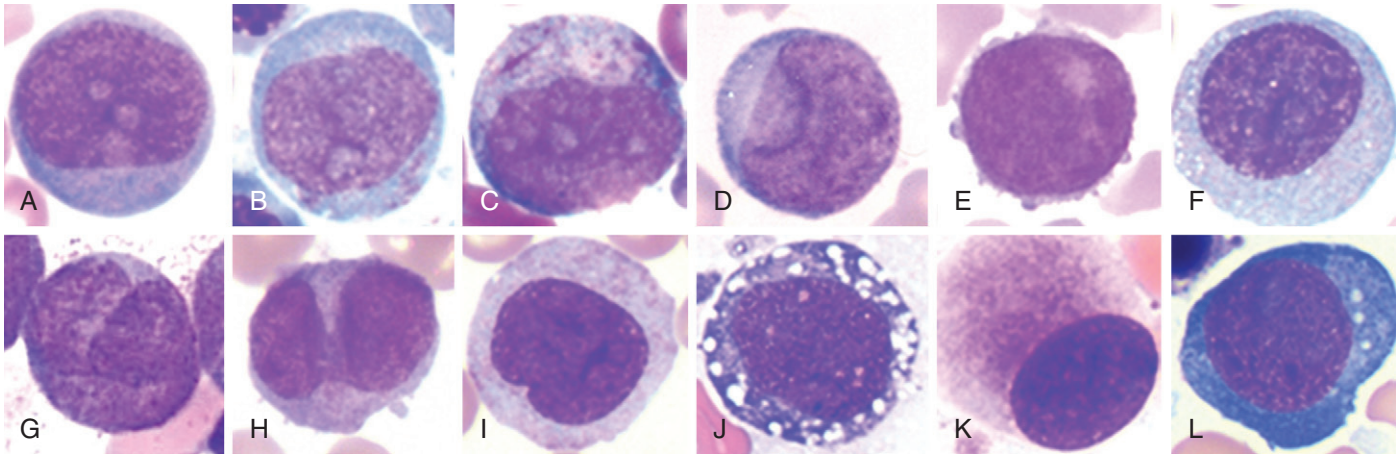

Figure 58-2 SPECTRUM OF BLASTS, BLAST EQUIVALENTS, AND OTHER CELLS. Blast cells in acute myeloid leukemia (AML) exhibit a wide spectrum of morphologic features. Initially, according to the French-American-British classification, there were three types of blasts depending on the granule content **(A** to **C).** However, blasts with nuclear invagination (frequently associated with NPM and/or Flt-3 mutations) **(D),** blasts with pseudopods (frequently shown to be megakaryoblasts) **(E),** and monoblasts **(F)** are also quite distinctive. Blast equivalents include granular or hypogranular promyelocytes **(G** and **H)** for acute promyelocytic leukemia, promonocytes **(I)** for AML with a monocytic component, and atypical pronormoblasts (frequently with cytoplasmic vacuoles) **(J)** for acute erythroleukemia of the pure erythroid type. Micromegakaryocytes **(K)** and pronormoblasts **(L)** are not considered blasts when considering AML.

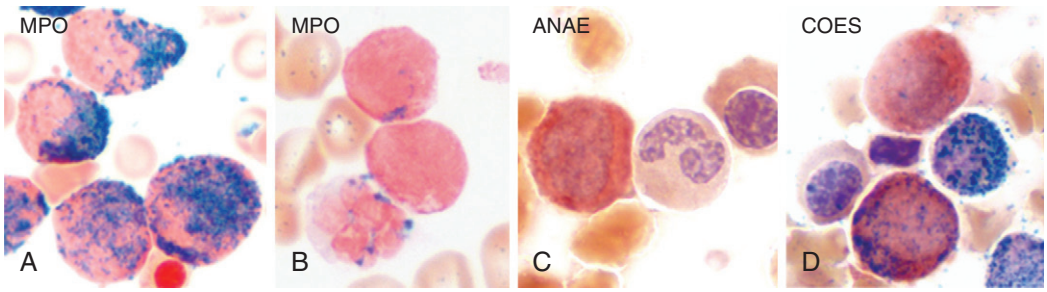

Figure 58-3 CYTOCHEMISTRIES: MYELOPEROXIDASE (MPO), α-NAPHTHYL ACETATE ESTERASE (ANAE), AND COMBINED ESTERASE (COES) REACTIONS. The MPO reaction is easily performed, can be done in less than a few minutes, and provides important initial information about the lineage of the blasts, particularly in cases in which morphologic assessment is difficult. In many laboratories it is routinely performed for all new acute leukemias. The MPO reaction should be interpreted in the blastic population and expressed as a percentage of blasts that are positive. **A,** The positive MPO reaction is strong. **B,** The reaction is weak and seen in only some blasts. A counterstain would have obscured the weak reaction product. A weak MPO reaction is not uncommon in cases of acute myeloid leukemia (AML) associated with myelodysplasia (as in **B**). The neutrophils in such cases are also only weakly positive (bottom cell, **B**). The ANAE reaction is a nonspecific esterase reaction positive in most monocytic cells (**C,** *orange-brown* cell on *left* compared to negative neutrophil, and erythroid cell, *middle* and *right*). The ANAE reaction is interpreted as positive cells as a percentage of nonerythroid elements. A significant monocytic component is usually defined as 20% or greater of the nonerythroid elements and is usually required for making a diagnosis of acute myelomonocytic leukemia. It is notable that in some cases of AML with inv(16) (i.e., AML with abnormal eosinophils), the monocytes are ANAE negative. A COES reaction uses another nonspecific esterase reaction for monocytes, α-naphthyl butyrate esterase, together with the specific esterase, chloroacetate esterase for granulocytes. The combination allows simultaneous evaluation of granulocytes (blue reaction product) and monocytes (orange-brown reaction product). **D,** Acute myelomonocytic leukemia. A monocyte *(top),* a granulocyte *(right),* and a myelomonocytic hybrid cell that exhibits both the orange-brown and blue reaction products *(bottom).*

CBFB-MYH11 (Fig. 58-5); AML with t(15;17)(q22;q12); PML-RARA (Fig. 58-6); and AML with t(9;11)(p22;q23), MLLT3-MLL (Fig. 58-7). However, this category now also includes cases with relatively uncommon genetic changes, and these are AML with t(6;9)(p23;q34), DEK-NUP214; AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2), RPN1-EVI1; and AML with t(1;22) (p13;q13), RBM15-MKL1 (Fig. 58-8). Provisional entities based on expression of exclusively molecular abnormalities have also been proposed, underlining the significance that molecular testing holds for the future, and these include AML with mutated nucleophosmin gene (NPM1; see Fig. 58-8, *G, H*), and AML with mutated CEBPA.. A second large category of AML is that of AML with myelodysplasia-related changes. These cases are defined in one of three ways: as AML in patients having a history of MDS, AML with multilineage dysplasia recognized morphologically (Fig. 58-9), or AML associated with a myelodysplastic-related cytogenetic abnormality. The next category in the classification is that of therapy-related AML. This category was retained from the 2001 WHO classification, although the distinctions between diseases associated with alkylating agents or radiation and those with topoisomerase II inhibitors were abandoned. Many patients receive complex therapeutic regimens including both types, making the initial distinction difficult. The next category of AML is a "wastebasket" of sorts for AML cases that do not fit the categories already described. These are considered "not otherwise specified" and for the most part are classified using the FAB classification (AML with minimal differentiation, AML without maturation, acute myelomonocytic leukemia, acute monocytic or monoblastic leukemia, acute erythroleukemia, acute megakaryoblastic leukemia,

Table 58-1 Classification of Acute Myeloid Leukemia According to the Revised World Health Organization Classification (2008)

Category	Subtype/Definition
AML with recurrent cytogenetic abnormalities	t(8;21)(q22;q22); RUNX1-RUNX1T1* inv(16)(p13.1q22); CBFB-MYH11* t(16;16)(p13.1q22); CBFB-MYH11* t(15;17)(q22;q12); PML-RARA* t(9;11)(p22;q23); MLLT3-MLL t(6;9)(p23;q34); DEK-Nup214 inv(3)(q21q26.2); RPN1-EVI1 t(3;3)(q21;q26.2); RPN1-EVI1 t(1;22)(p13q13); RBM15-MKL1
AML with MDS-related changes	Morphologic features of MDS, or Prior history of MDS or MDS/MPN, or MDS-related karyotype, and None of the recurrent genetic abnormalities above
Therapy-related myeloid neoplasms	Late complications of cytotoxic chemotherapy (alkylating agents, topoisomerase II inhibitors) and/or ionizing radiation therapy†
AML, not otherwise specified	AML with minimal differentiation AML without maturation AML with maturation Acute myelomonocytic leukemia Acute monoblastic/monocytic leukemia Acute erythroid leukemia Acute megakaryoblastic leukemia Acute basophilic leukemia Acute panmyelosis with myelofibrosis
Myeloid sarcoma	
Myeloid proliferations related to Down syndrome	Transient abnormal myelopoiesis Myeloid leukemia associated with Down syndrome
Blastic plasmacytoid dendritic cell neoplasm	
Acute leukemia of ambiguous lineage	Acute undifferentiated leukemia Mixed-phenotype acute leukemia with t(9;22)(q34;q11.2); BCR-ABL1 t(v;11q23); MLL rearranged Mixed-phenotype acute leukemia, B/myeloid, NOS Mixed-phenotype acute leukemia, T/myeloid, NOS
Provisional entities	AML with mutated NPM1 AML with mutated CEBPA NK-cell lymphoblastic leukemia/lymphoma

AML, Acute myeloid leukemia; *MDS,* myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm; *NK,* natural killer.
*Diagnosis of AML regardless of percentage of blasts.
†Excluded are patients with AML who have transformed from MPN.

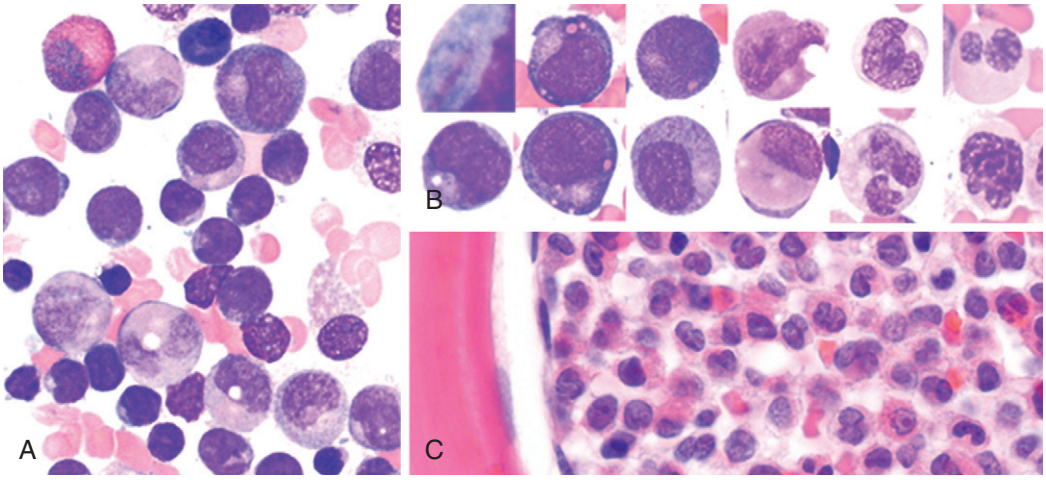

Figure 58-4 ACUTE MYELOID LEUKEMIA (AML) WITH t(8;21)(q22;q22), (RUNX1-RUNX1T1). **A,** Low-power, Wright-stained bone marrow aspirate smear showing increased blasts associated with differentiating myeloid cells. **B,** Details illustrating some of the features associated with this leukemia. They include blasts with long thin Auer rods *(top left),* immature cells with abnormal eosinophilic globules (*top* and *bottom, second from left*), abnormal salmon-colored granulation in the maturing cells, sometimes associated with a basophilic periphery (*top* and *bottom, fourth from left*), and slightly abnormal features in the mature neutrophils *(far right).* Pseudo–Chédiak-Higashi granules were not seen in this case. **C,** Biopsy specimen illustrates the significant degree of maturation that can sometimes be seen. In fact, in some cases the blast count can be less than 20%, but the diagnosis of AML can still be made with the cytogenetic finding of t(8;21).

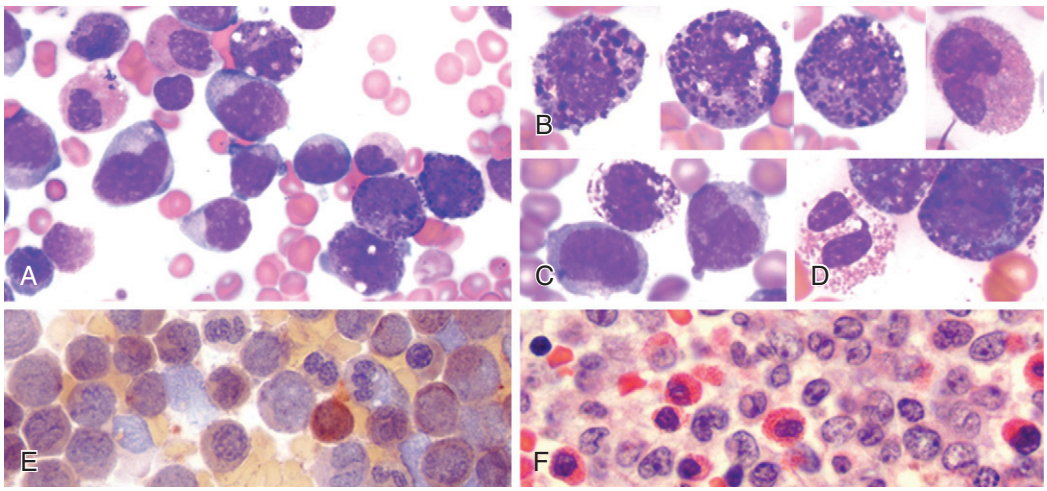

Figure 58-5 Acute myeloid leukemia (AML) with abnormal bone marrow eosinophils and inv(16)(p13.1;q22) or t(16;16)(p13.1;q22), (CBFB-MYH11). **A,** Low-power, Wright-stained bone marrow aspirate showing blasts, monocytic cells, granulocytic cells, and abnormal eosinophils. **B,** Features of the abnormal eosinophils in three abnormal eosinophils *(left three cells).* Note the abnormal basophilic granules in the eosinophilic myelocytes. These granules are large, tend to cluster or coalesce, and are interspersed among the large eosinophilic granules, which are more difficult to see. As the eosinophils mature, the abnormal basophilic granules are less prominent and sometimes disappear *(far right).* A common misconception is that the basophilic granules are the granules of basophils and that the abnormal eosinophils are "hybrid cells." This is not true. **C,** A basophil in the same case *(top cell)* for comparison. **D,** Some cells from a case of reactive eosinophilia, also for comparison. Immature eosinophils *(cell to the right)* do have primary blue granules. However, they are usually less prominent and less atypical than the basophilic granules of the abnormal eosinophils. It is notable that the monocytes in cases of AML with inv(16) or t(16;16) are sometimes α-naphthyl acetate esterase (ANAE)–reaction negative. **E,** Negative ANAE reaction. **F,** Abnormal eosinophils cannot be recognized in hematoxylin-eosin–stained sections of the biopsy.

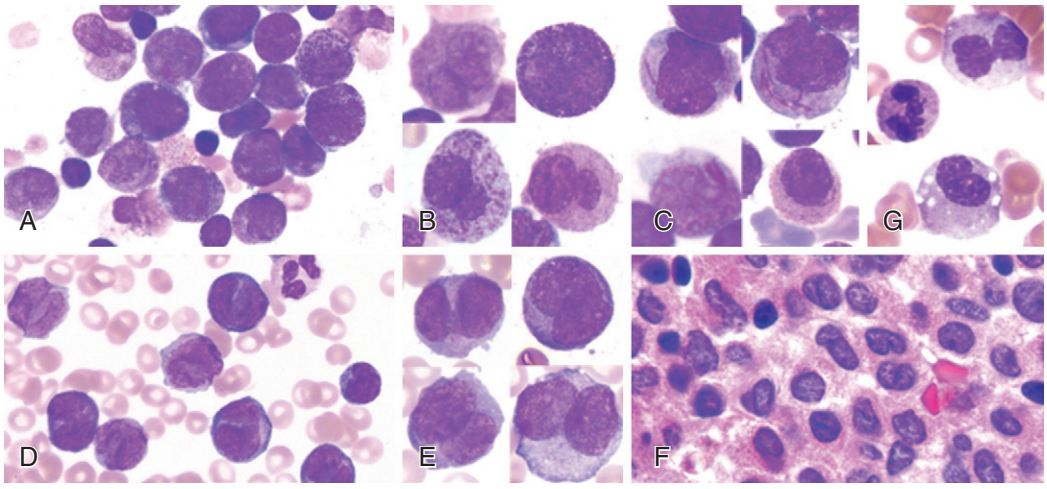

Figure 58-6 ACUTE PROMYELOCYTIC LEUKEMIA (APL), ACUTE MYELOID LEUKEMIA WITH t(15;17)(q22;q12)(PML-RARA). **A** to **C,** APL. **D** and **E,** Hypogranular or microgranular subtype. **F,** Bone marrow biopsy. **G,** APL cells maturing after all-trans retinoic acid (ATRA) therapy. In the typical granular type of APL **(A),** the abnormal promyelocytes can exhibit variable morphologic features. Even within the same case, the granules can range from coarse, dark, and dense to fine and dust-like **(B).** The nuclei in the abnormal promyelocytes frequently exhibit a bilobed, dumbbell, or reniform shape. This is a diagnostically important feature, which can sometimes be difficult to recognize beneath the granules **(B).** Auer rods can be single, multiple, coalesced into Auer bodies, and even present in maturing cells **(C).** The microgranular type usually presents with an elevated white blood cell count **(D).** Although granules cannot be readily appreciated at the light microscope **(E),** granules can be demonstrated by electron microscopy. The abnormal nuclear shapes (bilobed, dumbbell, and reniform) can be easily appreciated **(E).** Bone core biopsy sample typically shows sheets of cells with abundant granular cytoplasm **(F).** After ATRA therapy the abnormal promyelocytes mature to abnormal neutrophils (**G,** *top and bottom right,* compared to normal neutrophil, *left*). These can be seen for weeks after therapy and do not signify a failed response to the differentiating agent.

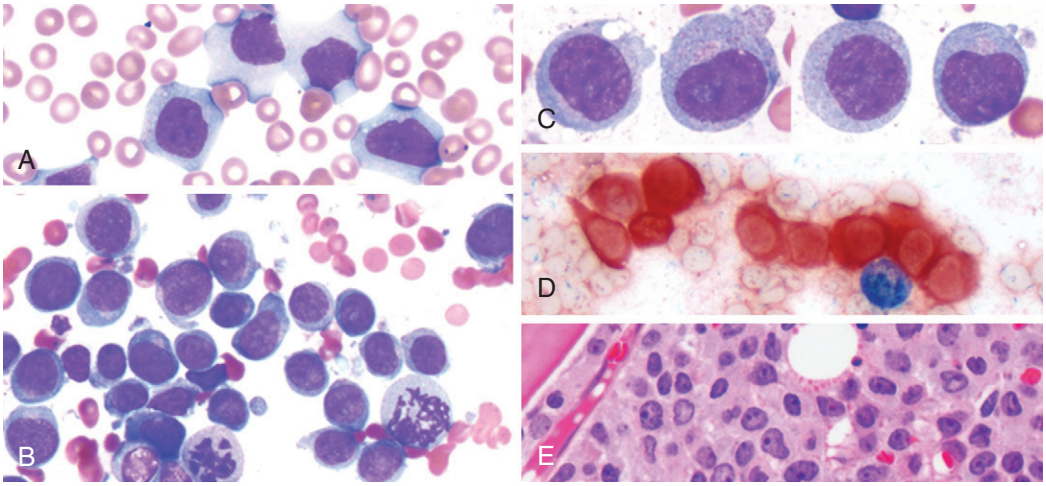

Figure 58-7 ACUTE MONOBLASTIC LEUKEMIA WITH t(9;11)(p22;q23), (MLLT3-MLL). Acute monoblastic leukemia with t(9;11). **A,** Such cases typically present with high counts because of circulating monoblasts. **B, C,** Bone marrow aspirate is packed with monoblasts and shows few granulocytic elements. **D,** Absence of a granulocytic component can be illustrated with the combined esterase reaction, in which most of the cells show the α-naphthyl butyrate reaction product *(orange-brown),* with only rare granulocytes with the blue reaction product from the chloroacetate esterase reaction. **E,** The biopsy sample is usually packed with sheets of monoblasts with fine nuclear chromatin and abundant pink cytoplasm.

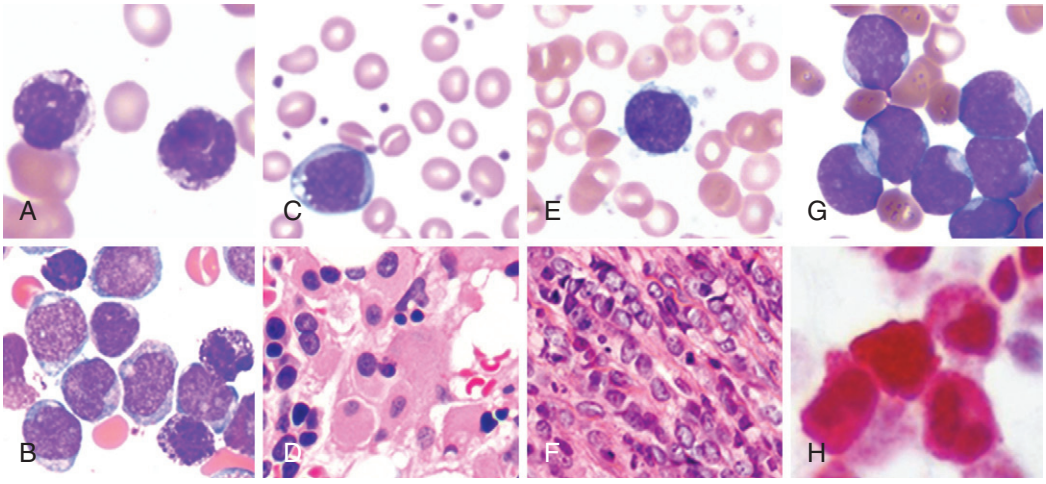

Figure 58-8 ACUTE MYELOID LEUKEMIA (AML) WITH LESS-COMMON CYTOGENETIC AND GENETIC CHANGES. **A** and **B,** AML with t(6;9)(p23;q34). These cases are characterized by marrow dysplasia and basophilia. However, the morphologic characteristics can be quite varied among cases. AML with inv(3)(q21q26.2) or t(3;3)(q21;q26.2) is characterized by normal or high platelet counts **(C)** and by a bone marrow with numerous micromegakaryocytes **(D).** AML with t(1;22)(p13;q13) is uncommon and occurs in infants. The blasts are megakaryoblasts **(E)** but in the bone marrow can have a sarcomatous appearance **(F).** AML with NMP or NPM and Flt-3 mutations frequently presents with high peripheral blasts counts, and the blasts sometimes have nuclear invaginations **(G).** NPM mutation is associated with the abnormal cytoplasmic localization of NPM rather than the normal nuclear staining **(H).**

AML with maturation, acute basophilic leukemia). The AML-like disease of acute panmyelosis with myelofibrosis is included in this group (Fig. 58-10). Lastly, the classification now includes myeloid sarcoma (Fig. 58-11), myeloid proliferations associated with Down syndrome (see Chapter 62), and the unusual blastic plasmacytoid dendritic cell neoplasm. The latter is an aggressive malignancy of plasmacytoid dendritic cells that frequently involves the blood and bone marrow (Fig. 58-12).

Prognostic factors are best divided into patient-related features that predict likelihood of surviving induction chemotherapy and disease-related factors that determine resistance to chemotherapy.[3] Among the former, age, performance status, and basic assessment of organ function (hepatic, renal, cardiac) have the greatest impact. Comorbidity scores such as the hematopoietic cell transplantation comorbidity index (HCTCI) have been applied to identify patients unfit for chemotherapy and may be particularly useful in older patients. Resistance to therapy is determined by presence or absence of an antecedent hematologic disorder such as MDS, exposure to previous chemotherapy and/or radiation therapy (therapy-related AML), and biologic features of the blasts themselves. Among the latter, karyotype continues to be the most important pretreatment prognostic feature dividing patients into those with favorable (CBF leukemias associated with t(8;21) and inv(16) or t(16;16); APL with t(15;17)), unfavorable (complex abnormalities, monosomies such as -5 and -7 among others), and intermediate prognosis (mainly diploid) (Fig. 58-13).[4] The prognostic power of karyotype is nowadays augmented by including molecular abnormalities. Genotype analysis adds most in patients with normal cytogenetics. Many molecular markers are being investigated (e.g., Flt-3, NPM1, CEBPA, Ras, KIT, IDH1 and IDH2, MLL, TET2). Testing for NPM1, CEBPA, and

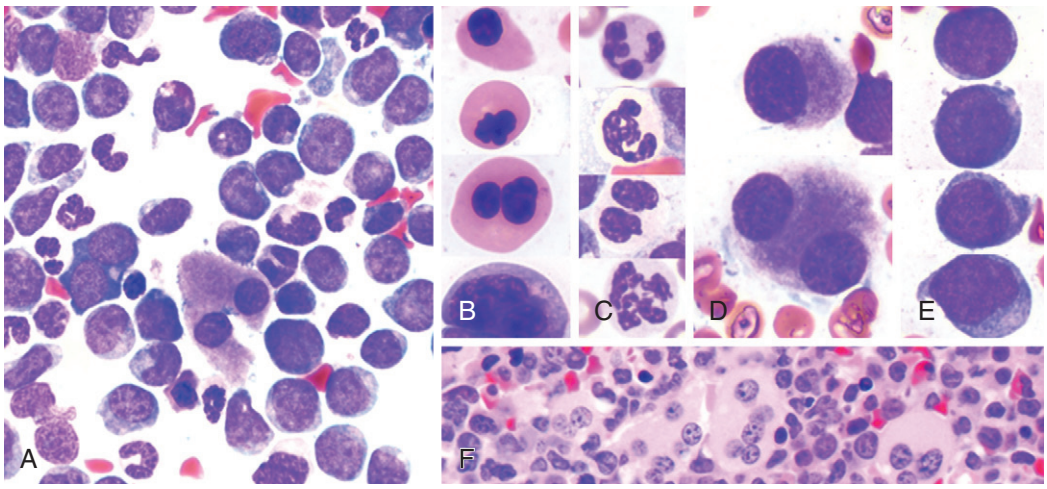

Figure 58-9 ACUTE MYELOID LEUKEMIA WITH MULTILINEAGE DYSPLASIA. **A,** Bone marrow aspirate shows increased blasts and maturing cells with dysplastic features. **B** to **D,** Details of the dysplasia. **B,** Maturing erythroid elements exhibit megaloblastoid change and bizarre nuclear abnormalities. **C,** Dysplastic granulocytes *(bottom three)* are compared to a rare normal granulocyte *(top)*. The dysplastic forms have pale cytoplasm and abnormal nuclear shapes with hypolobation, hypersegmentation, and prominent nuclear excrescences. **D,** Dysplastic micromegakaryocytes have single or double small nuclei but mature cytoplasm with platelet material within. **E,** Increased blasts. **F,** Dysplasia is difficult to appreciate on a biopsied section. This is true except for the megakaryocytes. Dysplastic megakaryocytes can be recognized on the biopsy specimen by their abnormally small nuclei, which are sometimes multiple and widely spaced.

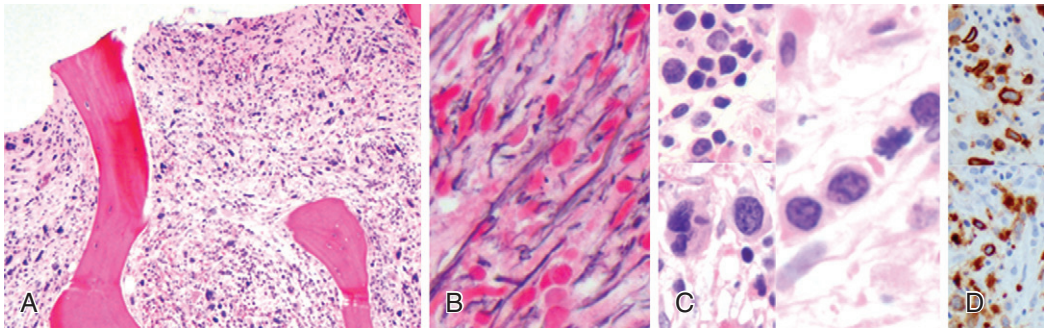

Figure 58-10 ACUTE PANMYELOSIS WITH MYELOFIBROSIS. **A,** Bone marrow biopsy specimen shows a loosely packed marrow with a swirling appearance to the cellular elements due to underlying fibrosis. **B,** The latter is illustrated on the reticulin stain. **C,** Proliferations of erythroid cells *(top left),* megakaryocytes *(bottom left),* and immature cells within the fibrotic areas *(right)*. **D,** Immunohistochemical staining shows increased megakaryocytes (*top,* CD61) and increased blasts (*bottom,* CD34).

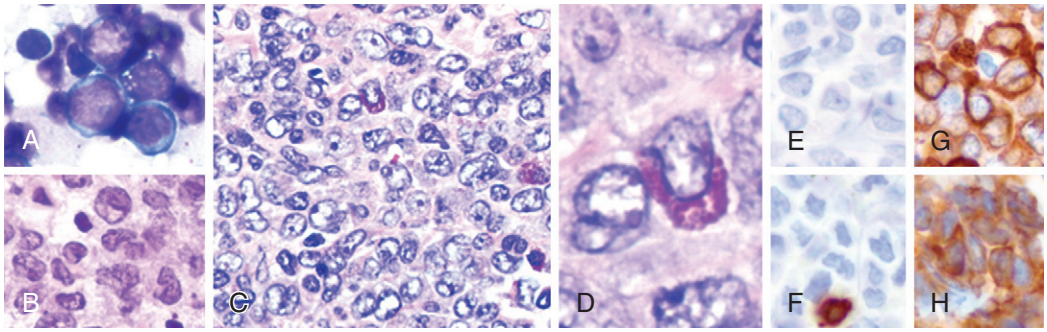

Figure 58-11 MYELOID SARCOMA. Myeloid sarcomas can sometimes present a diagnostic challenge. In this case the touch imprints **(A)** and frozen section preparation **(B)** from a mass lesion in the cecal area from a 44-year-old patient were thought to represent a high-grade lymphoma. However, initial immunohistochemical stains did not support the diagnosis, and on closer inspection of the tumor and with subsequent immunomarkers, a diagnosis could be reached. The tumor **(C)** is composed of sheets of noncohesive cells. A diagnostic clue to the origin was the presence of eosinophilic myelocytes **(D),** which indicate that some tumor cells have the capacity to differentiate to eosinophils. The granules of neutrophilic myelocytes cannot be recognized on tissue section. The immunohistochemical stains showed the cell to be CD45+ (not shown), B, and T marker negative **(E** and **F),** but myeloid marker (myeloperoxidase and CD33) positive **(G** and **H).** Cytogenetic analysis showed the case was inv(16)(p13.1;q22).

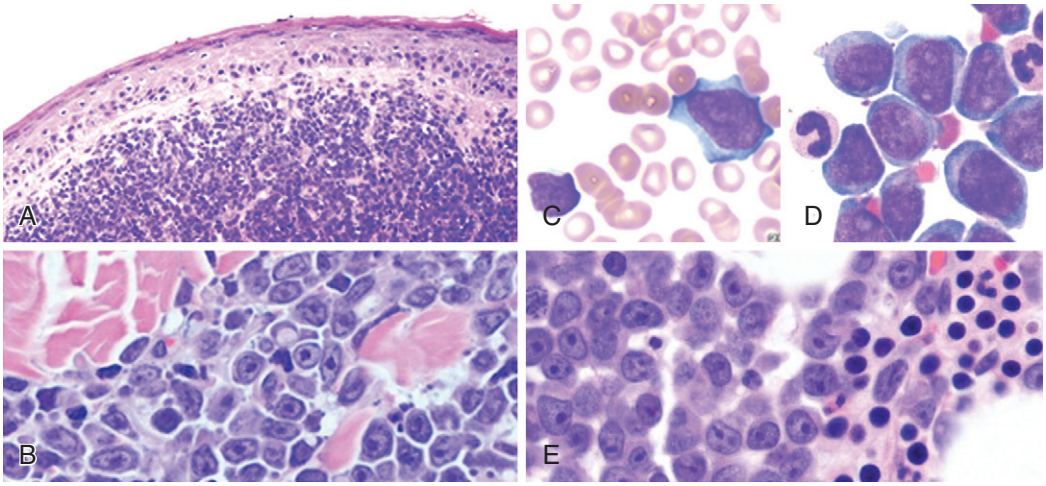

Figure 58-12 BLASTIC PLASMACYTOID DENDRITIC CELL NEOPLASM. The blastic plasmacytoid dendritic cell tumor is an unusually aggressive malignancy that was previously called *hematodermic* malignancy. It is now classified in the acute myeloid leukemia category of myeloid neoplasms. It frequently presents in the skin with a blastic proliferation of cells in the dermis **(A** and **B),** which inevitably spreads to the blood **(C),** and bone marrow **(D** and **E).**

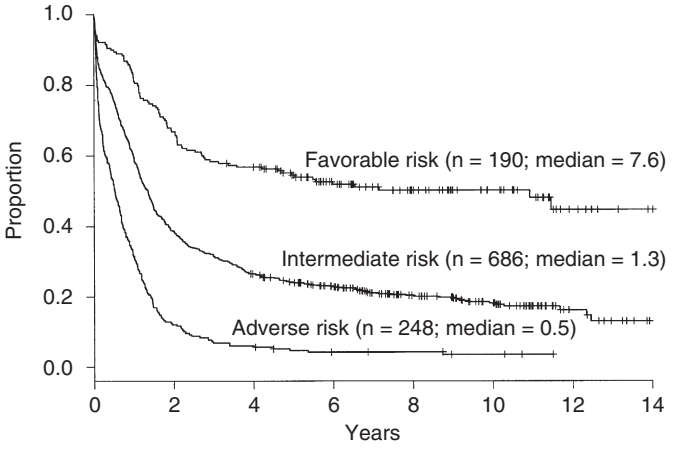

Figure 58-13 DISEASE-FREE SURVIVAL BY CYTOGENETIC RISK GROUP. *(Data from Byrd JC, Mrózek K, Dodge RK, et al: Pretreatment cytogenetic abnormalities are predictive of induction success, cumulative incidence of relapse, and overall survival in adult patients with de novo acute myeloid leukemia: Results from Cancer and Leukemia Group B (CALGB 8461),* Blood *100:4325, 2002.)*

Flt-3 mutations is recommended today in general practice. A panel on behalf of the European LeukemiaNet has proposed a standardized reporting for correlation of cytogenetic and molecular genetic data.[1]

THERAPY FOR ACUTE MYELOID LEUKEMIA

AML therapy is one of the most challenging of oncologic interventions (Fig. 58-14). Interventions often need to be fast, physicians need to deal with a multitude of complications (disease or treatment related), and any patient's condition can change rapidly. Given its complexity, treatment of patients with AML requires a multidisciplinary effort including oncologists, pharmacists, specifically educated nursing staff, and various consulting services (infectious disease, pulmonology, nephrology, cardiology). Supportive care is an essential part of AML therapy and plays an ever more important role, including transfusion services and symptom control measures.

The general approach to AML therapy depends on the AML subtype (APL, CBF leukemias, other) as well as age and performance status of the patient (high-intensity versus low-intensity therapy). Treatment of older patients (generally defined as older than 60 to 65 years) increasingly differs from that of younger patients, and hence this chapter follows this development by addressing the two age groups separately.

Treatment of AML consists of induction and postremission therapy. The goal of induction is to produce a complete remission (CR) and that of postremission therapy to maintain it by eliminating residual disease. CR is defined as achievement after chemotherapy of less than 5% marrow blasts, a neutrophil count of greater than 1000/μL, a platelet count of greater than 100,000/μL, independence of red blood cell transfusions, and resolution of all signs and symptoms referable to AML. CR defines a landmark point in time because patients who achieve CR on any given day after beginning therapy have longer survival subsequent to that day than patients who are resistant to therapy on the day in question. Lesser response criteria (CR without platelet recovery, CR with incomplete blood recovery including neutropenia, partial remission, morphologic leukemia-free state) may serve as useful end points in the context of investigational studies (phase I, II, or III), but they do not carry the same significance for survival as does CR. Postremission therapy consists of repeated cycles of chemotherapy or hematopoietic stem cell transplantation (HSCT) in its various forms (autologous, allogeneic, haploidentical, cord blood, reduced intensity). The role of HSCT for AML therapy will be the topic of a separate chapter of this book. The debate as to which patients should receive chemotherapy consolidation versus HSCT is most divisive for patients with intermediate-risk disease. In this population, characterization of the genotype has become most helpful in guiding that decision.

Leukemia has been at the forefront of the development of "targeted" therapy, mostly small-molecule drugs directed against defined intracellular proteins (e.g., kinases). Not surprisingly, given the increasing number of genetic changes and the identification of diverse signaling pathways of leukemic blasts, the specter of "personalized therapy" also looms high in AML therapy. Despite intense research activity, to date no "targeted" drug has been approved for this indication (with the exception of gemtuzumab ozogamicin [GO], an anti-CD33 monoclonal antibody–calicheamicin conjugate with activity in some subtypes of AML, but whose approval was recently revoked by the Food and Drug Administration [FDA]).

Therapy for Younger Adults

Standard Induction Therapy

Induction therapy is based on the combination of cytarabine and an anthracycline. Cytarabine, an analogue of a physiologic pyrimidine

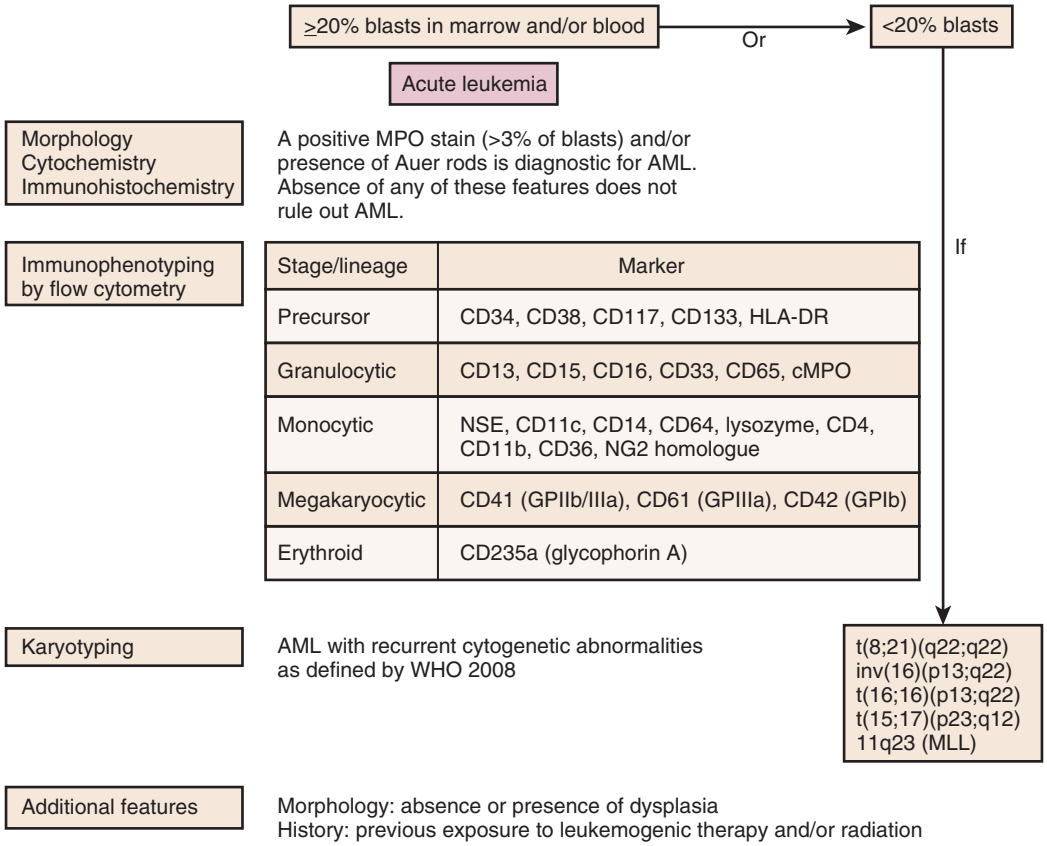

Figure 58-14 GENERAL DIAGNOSTIC APPROACH TO ACUTE MYELOID LEUKEMIA THERAPY. *AML,* Acute myeloid leukemia; *APL,* acute promyelocytic leukemia; *ATRA,* all-trans retinoic acid; *CBF,* core binding factor; *FLAG,* fludarabine, cytarabine (ara-C), and granulocyte colony-stimulating factor.

nucleoside, is an antimetabolite that requires intracellular conversion to its triphosphate compound, ara-CTP, and incorporation into deoxyribonucleic acid (DNA) to become active. When given by itself at standard doses of 100 to 200 mg/m^2 intravenously (IV) daily for 5 to 7 days, it produces CR rates of around 40%. Anthracyclines (daunorubicin, idarubicin, aclarubicin) act by stabilizing the normally occurring complex between DNA and the enzyme topoisomerase II, thereby leading to apoptotic cell death. Daunorubicin, the most frequently used anthracycline, achieves similar CR rates as with cytarabine alone. The combination of cytarabine at 100 to 200 mg/m^2 as a continuous IV infusion (its serum half-life is only 15 minutes) daily for 7 days and daunorubicin at 45 to 60 mg/m^2 IV daily for 3 days on days 1 to 3 has become known as the "3+7" regimen and, for more than 40 years, has been the standard induction combination for most patients with AML. Remission rates range from 60% to 80%, and long-term disease-free survival is about 35%.[5] Patients who fail to achieve remission may be divided into those who die during induction, mainly as a consequence of multisystem organ failure in the wake of infections, and those who survive induction therapy but whose blasts remain resistant to chemotherapy regardless of whether or not marrow hypoplasia was achieved during treatment. Whereas induction mortality is low among patients younger than 50 years, it can increase substantially in older patients.

In clinical practice, patients undergo a repeat marrow study between 14 and 21 days from the start of treatment (Fig. 58-15). If the marrow continues to show blasts and is cellular, a reinduction is usually given. The reinduction may be a repetition of the induction, be it attenuated (e.g., "2+5") or intensified as intermediate-dose cytarabine (IDAC) or high-dose cytarabine (HiDAC). If the day 14 or 21 marrow is hypoplastic, supportive care continues and marrow studies are repeated every 1 to 2 weeks until it becomes clear whether the patient is going into CR or not. If in CR, postremission therapy starts shortly thereafter, whereas in case of no response, treatment is often changed. Although reinductions lead to remissions, these are usually shorter lasting. The degree of neutrophil and platelet recovery at the time of remission has prognostic significance. Higher neutrophil and platelet counts at the time of remission are predictive of better relapse-free survival. In some cases a regenerating marrow may have an increased number of blasts, which may look like persistent leukemia. Further follow-up marrow studies will show reduction in blasts concomitant with a rise of neutrophils and platelets.

Many modifications to the 3+7 regimen have been tried to improve outcome. Giving 10 instead of 7 days of cytarabine (3+10), increasing the dose of cytarabine from 100 mg/m^2/day to 200 mg/m^2/day, adding a third drug (e.g., mitoxantrone, etoposide, thioguanine, topotecan, fludarabine) or modulators of drug resistance, and priming leukemic blasts with hematopoietic growth factors (granulocyte colony-stimulating factor [G-CSF], granulocyte-macrophage colony stimulating factor) are not any better and not recommended. Giving cytarabine as a continuous infusion rather than twice-daily, short IV infusions achieved slightly better response rates.

The choice of anthracycline has been the subject of an ongoing debate. Substitution of daunorubicin by doxorubicin produced more toxicity without added benefit. In three randomized trials of idarubicin versus daunorubicin, the combination of idarubicin with cytarabine produced higher response rates and a survival advantage in at least one study. However, most would nowadays agree that daunorubicin 45 mg/m^2 daily for 3 days is not appropriate and no longer standard of care in AML.[6] Recent studies analyzed the impact of higher doses of daunorubicin on AML induction outcome. A large study from Japan randomly assigned 1057 newly diagnosed patients with AML under 65 years to receive daunorubicin 50 mg/m^2 daily for 5 days or idarubicin 12 mg/m^2 daily for 3 days in combination with cytarabine 100 mg/m^2 by continuous IV infusion daily for 7 days. There were no differences in CR (77.5% versus 78.2%, P = .79), 5-year overall survival (48% in both groups, P = .54), or 5-year

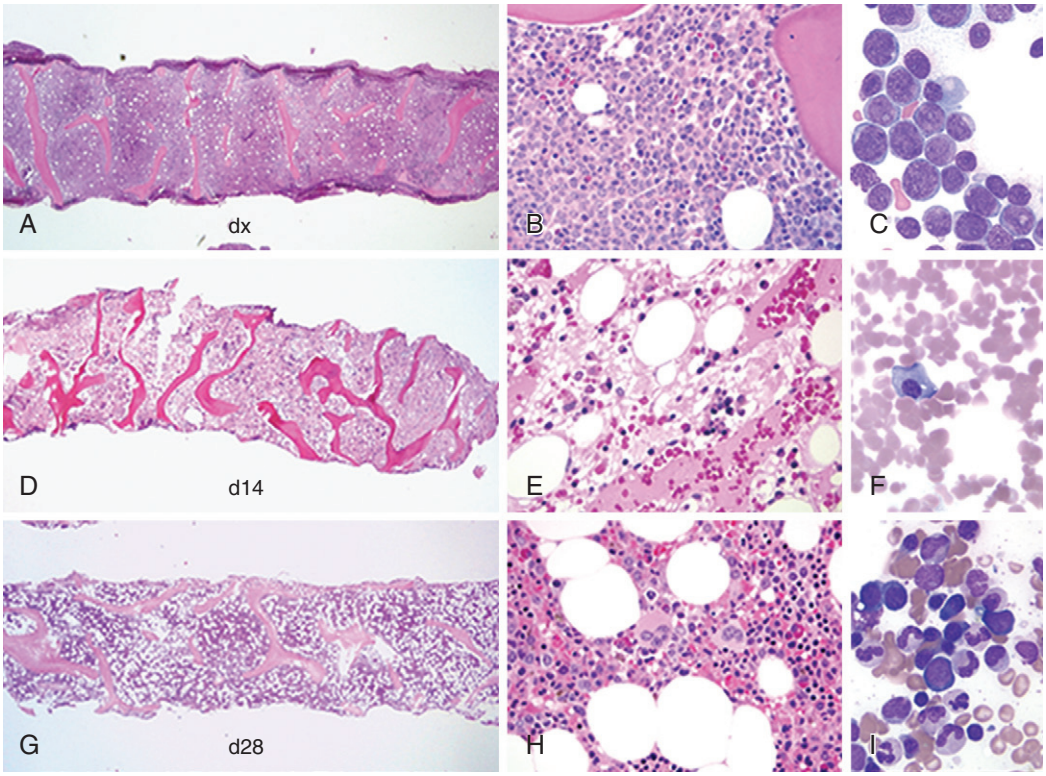

Figure 58-15 Acute myeloid leukemia at diagnosis and at day 14 and day 28 following the start of standard induction chemotherapy. A 43-year-old man presented with fatigue and was found to have a white blood cell count of 70,300/μL composed of mostly blasts. A bone marrow study **(A** to **C)** showed a hypercellular bone marrow (90% cellular) packed with blasts (80%). The blasts were myeloperoxidase positive and had the following phenotype: CD34+, HLA-DR+, CD117+, CD13+, CD33+ with partial CD15 and CD11b. Cytogenetic analysis demonstrated a normal male karyotype, and molecular studies showed wild-type Flt-3 and NPM1. The patient was treated with standard induction chemotherapy, and a day 14 bone marrow study **(D** to **F)** showed chemoablation effects with an empty marrow, stromal injury, dilated sinuses, and only scattered stromal cells and plasma cells with no obvious blasts. A bone marrow study performed at day 28 **(G** to **I)** showed regenerative changes with trilineage hematopoiesis.

relapse-free survival (41% in both groups, $P = .97$).[7] The French ALFA-9801 study randomized AML induction patients (age 50 to 70 years) to one of three anthracycline arms: daunorubicin 80 mg/m^2 daily for 3 days and idarubicin 12 mg/m^2 daily for 3 days and 4 days, respectively. Complete remission rates favored idarubicin (83%, 78%, and 70% for idarubicin × 4, idarubicin × 3, and daunorubicin, respectively, $P = .04$), and there was a trend for better survival.[8] A study by the Eastern Cooperative Oncology Group (ECOG) randomized patients between the ages of 17 and 60 years with untreated AML to receive the 3+7 combination with either standard-dose daunorubicin (45 mg/m^2 daily × 3) or high-dose daunorubicin (90 mg/m^2 daily × 3).[9] High-dose daunorubicin achieved higher rates of CR (70.6% versus 57.3%, $P<.001$) and improved median overall survival (23.7 months versus 15.7 months, $P = .003$), an improvement limited to patients younger than 50 years and with intermediate cytogenetics. High-dose daunorubicin did not lead to a higher incidence of adverse events (particularly cardiomyopathy and infectious complications). In conclusion, rather than the type of anthracycline, what matters most is to use an adequate dose.

HiDAC as part of the induction has been investigated in several randomized trials. A metaanalysis of trials encompassing 1691 patients arrived at the following conclusions: there were no differences between HiDAC and standard-dose cytarabine (SDAC) with respect to percent CR and rates of persisting leukemia and early death; 4-year overall and recurrence-free survival, on the other hand, were significantly better with HiDAC but at the cost of more toxicities (infections, nausea/vomiting, CNS).[10] HiDAC benefited mostly patients who already were more likely to achieve CR (i.e., patients with intermediate and favorable karyotype). The major drawback of HiDAC during induction is that it may make further consolidation therapy difficult. The Medical Research Council (MRC) AML 15 trial randomized 635 patients to receive fludarabine, cytarabine (ara-C), G-CSF, and idarubicin (FLAG-Ida; fludarabine 30 mg/m^2 on days 2 to 6, cytarabine 2 g/m^2 on days 2 to 6, idarubicin 10 mg/m^2 on days 4 to 6, and G-CSF on days 1 to 7) and 631 to receive cytarabine (ara-C), daunorubicin, and etoposide (ADE; daunorubicin 50 mg/m^2 on days 1, 3, 5; cytarabine 100 mg/m^2 on days 1 to 8; and etoposide 100 mg/m^2 on days 1 to 5), the latter representing the SDAC arm.[11] While there were no significant differences in response rate, fewer patients on FLAG-Ida relapsed. However, more myelosuppression and deaths in CR offset the survival benefit. A recent study by the Dutch-Belgian Cooperative Trial Group for Hemato-Oncology (HOVON) and the Swiss Group for Clinical Cancer Research (SAKK) Collaborative Group randomized patients with newly diagnosed AML (ages 18 to 60 years) to HiDAC (cytarabine 1 to 2 g/m^2) or IDAC (cytarabine 0.2 to 1 g/m^2).[12] HiDAC provided no advantage in any prognostic subgroup but resulted in more severe adverse events, prolonged hospitalizations, and delayed neutrophil and platelet recovery. HiDAC during induction remains investigational.

Standard Postremission Therapy

Once in a morphologic CR, there are still as many as 10^9 leukemia cells present below the threshold of detection by light microscopy (minimal residual disease). Further therapy is therefore necessary to reduce this number and minimize the chances of relapse. In a series

of clinical studies in which patients did not receive postremission therapy, relapse was universal, and the median remission duration was about 4 months.

There is still debate about details of postremission therapy with regard to dose, number of cycles, or whether or not there is a role for maintenance. In a classic Cancer and Leukemia Group B (CALGB) study patients with newly diagnosed AML received the 3+7 combination and once in CR were randomized to SDAC (100 mg/m^2 continuous IV infusion daily × 5), IDAC (400 mg/m^2 continuous IV infusion daily × 5), or HiDAC (3 g/m^2 IV over 3 hours every 12 hours on days 1, 3, and 5) for a total of four cycles. This was followed by an additional four cycles of 2+5, a consolidation-maintenance omitted from all subsequent CALGB studies. The probability of remaining in continuous CR after 4 years was 24% for SDAC, 29% for IDAC, and 44% for HiDAC ($P = .002$). Among several randomizations in the AML MRC12 trial 1193 patients received induction therapy with either standard-dose daunorubicin, cytarabine (ara-C), and thioguanine (S-DAT) or double the standard dose of cytarabine (H-DAT).[13] In consolidation, patients then received either a total of four or five courses (including induction). There was no difference in outcome between the induction arms, and no difference for the addition of a fifth course. The Japan Adult Leukemia Study Group (JALSG) conducted a randomized study in 781 patients younger than 65 years in CR who received either three courses of HiDAC (2 g/m^2 IV twice daily for 5 days) or four courses of conventional standard-dose multiagent chemotherapy.[14] There was no difference between the groups with respect to 5-year disease-free survival (43% versus 39%, $P = .724$) or 5-year overall survival (58% versus 56%, $P = .954$). The study showed a beneficial effect of HiDAC only in the group of patients with favorable cytogenetics.

HiDAC in consolidation benefits mostly patients who are younger than 60 years and those with favorable cytogenetics, but to a far lesser extent those with intermediate and unfavorable karyotypes. Postremission therapy should be guided by the risk profile of the patient (based on cytogenetics and genotype; Table 58-2).

CBF leukemias are characterized by translocation t(8;21), inv(16), or t(16;16) and at the molecular level by a disruption of CBF transcription genes, which play a crucial role in hematopoietic differentiation. CBF AMLs occur in about 15% of patients with AML. CBF AMLs are very sensitive to cytarabine-based therapy. Remission rates are close to 90%, and long-term overall survival reaches 60%. Postremission therapy with HiDAC (e.g., 3 g/m^2 IV every 12 hours on days 1, 3, and 5) for three to four cycles is considered adequate. Some questions persist with regard to the optimal number of cycles, intensification, and addition of further drugs. One cycle (with a cumulative dose of up to 18 g/m^2 of cytarabine) is worse than three or four cycles (cumulative dose 54 mg/m^2 to 72 mg/m^2). On the other hand, giving two cycles in combination with idarubicin, daunorubicin, or mitoxantrone is comparable to three or four cycles with HiDAC. According to the MRC AML10 trial, one consolidation cycle of IDAC (cumulative dose of 5 g/m^2) was equivalent to three or four consolidation cycles as given in the CALGB studies. In recent studies, the addition of gemtuzumab (GO) to cytarabine-based conventional chemotherapy was shown to improve survival for patients with a favorable karyotype.[15] Given the excellent responsiveness to chemotherapy vis-à-vis the higher risk for treatment-related mortality and morbidity with stem cell transplant, there is no well-established role for transplant as consolidation for CBF AML. Some patients with CBF AML fare worse despite the apparent favorable karyotype. Long-established poor prognostic factors include older age, a high WBC at presentation, presentation with granulocytic sarcoma and t(8;21), and expression of CD56. An important factor associated with worse survival is the presence of KIT mutations. Mutations of KIT (more frequently of exon 17 than exon 8) occur in up to one-third of patients with inv(16) and about 20% of those with t(8;21). Although remission rates do not differ, relapse is more likely with mutated than wild-type KIT. Screening for KIT mutations should routinely follow cytogenetic analysis. Leukemic blasts with activated KIT could be targeted with novel tyrosine kinase inhibitors. Given the higher relapse rate, allogeneic stem cell transplant in this situation is also advocated by some.

Patients with diploid cytogenetics and mutations of either NPM1 or biallelic mutations of CEBPA in the absence of Flt-3/ITD (fms-related tyrosine kinase 3 gene/internal tandem duplication) have a similarly favorable outcome to that of patients with CBF AML (without mutations of KIT) and are not referred for HSCT in first remission. There is also evidence that patients with mutations of Ras benefit from higher doses of cytarabine. Whether or not this obviates the need for a transplant in remission is not clear.

Patients with intermediate-risk AML are the largest group (about 60% of AML). These patients are induced with the 3+7 combination followed by up to four cycles of HiDAC (3 g/m^2 IV twice daily on days 1, 3, and 5) in consolidation. Because long-term disease-free survival remains suboptimal, there is an ongoing debate about how to approach these patients, and in particular the role of transplant.[16] Most randomized studies in the past demonstrated similar overall survival whether patients received intensive consolidation therapy, autologous, or allogeneic HSCT, where an improvement of relapse likelihood following transplant was offset by a higher transplant-related mortality. According to a more recent metaanalysis of 24 prospective trials including 6007 patients evaluating allogeneic HSCT versus nonallogeneic HSCT therapies for AML in first CR, both relapse-free survival and overall survival were significantly better for patients with intermediate- and poor-risk AML if they underwent allogeneic HSCT. The intermediate-risk group is heterogeneous, and the prognosis of patients with cytogenetically normal karyotype differs widely. Identification of gene mutations is helpful to gauge prognosis and, within a limited scope, to guide therapy. Although data are sparse, transplant can be deferred in patients with cytogenetically normal karyotype and favorable genotype (mutations of NPM1 or biallelic mutations of CEBPA without Flt-3/ITD). On the other hand, transplant in first CR should be considered in patients with unfavorable genotypes (e.g., Flt-3/ITD abnormalities). The presence of a Flt-3/ITD mutation may not matter as much as the mutated allele burden, so that quantification will likely play an increasing role. The picture is even less clear in most of the other mutations, for which data remain sparse and conflicting.

Outcome remains dismal for patients with adverse-risk cytogenetics. These patients have a low cure rate with standard chemotherapy and should be referred for transplant or clinical trials if available.

Table 58-2 Postremission Therapy by Cytogenetic-Molecular Profile

Prognostic Group	Subgroups	Chemotherapy (HiDAC)	HSCT
Favorable		Yes	No
	KIT+ CBF	Yes	Yes
Intermediate		Yes	Yes
	Flt-3/ITD+	Yes	Yes
	Flt-3/D835+	Yes	No
	NPM1+*	Yes	No
	CEBPA+*	Yes	No
	NPM1-Flt-3/ITD+	Yes	Yes
Unfavorable		No	Yes

*Without concomitant expression of Flt-3/ITD or IDH1. In the case of CEBPA, only if the mutation is biallelic.
HiDAC, High-dose cytarabine; *HSCT,* hematopoietic stem cell transplant.

Therapy for Older Patients

Although arbitrary, *older* usually refers to patients who are 60 years and above. In an analysis of Surveillance, Epidemiology, and End Results (SEER) cancer registries and Medicare administrative claims,

the estimated median survival of 2657 older patients with AML was 2 months with a 2-year survival rate of 6%.[17] However, only one-third of patients received treatment for AML, assuming that therapy was considered futile and palliation more appropriate. Older patients do worse for various reasons. Comorbidities are frequent, and they are more likely to have a poor performance status. Hence tolerance to intensive chemotherapy and its myelosuppressive and immunosuppressive consequences is diminished. There are also differences intrinsic to the biologic behavior of AML blasts in older and younger patients. Patients over age 60 are more likely to have secondary AML (following MDS), express unfavorable cytogenetics, and have reduced sensitivity to anthracyclines, and they more often express multidrug-resistant phenotypes. Nevertheless, older patients should not be precluded from therapy. As the SEER analysis also showed, patients who were treated lived on average 6 months longer. Other studies have also demonstrated the benefits of induction therapy over supportive care only, with respect to survival and quality of life.

Induction Therapy for Older Patients

Three options are conventional chemotherapy, clinical trials, and palliative care. Given the poor outcome with conventional therapy (median survival 10 months; induction mortality around 20%, which may exceed 50% in patients with a poor performance status), it can be argued that almost no one in this age-group should be treated with conventional therapy. Yet older patients are not a homogenous group, and outcome varies. Several prognostic models have been designed to identify patients who may do well with conventional therapy versus those who will not (Table 58-3). These models are based on easily accessible clinical information but are mainly derived from retrospective analyses and require validation in prospective clinical trials.

Among conventional therapy, low-intensity approaches can be distinguished from intensive (i.e., standard-dose cytarabine) therapy. Low intensity is indicated for patients who are "unfit" for chemotherapy, that is, who are older (e.g., older than 70 to 75 years), have a limited performance status, and at the same time do not display disease features (adverse karyotype, treatment-related AML) with a high likelihood of resistance. In the National Cancer Research Institute AML 14 Trial, 217 patients considered unfit for intensive chemotherapy were randomized to low-dose cytarabine at 20 mg subcutaneously twice daily for 10 days or hydroxyurea.[18] Both survival and remission rate (18% versus 1%; $P < .001$) were superior with low-dose cytarabine with the exception of patients with adverse cytogenetics, who did poorly on either treatment arm. Hypomethylating agents are widely used in the treatment of myeloid disorders such as MDS and increasingly in AML. Azacitidine 75 mg/m^2 subcutaneously daily for 7 days was compared to conventional care (best supportive care, low-dose cytarabine, or intensive chemotherapy) in a subset of 113 patients (median age 70 years) entered on a randomized MDS study but had 20% to 29% blasts.[19] Median overall survival was 24.5 months in the azacitidine group and 16 months in the conventional care group ($P = .005$). The median survival of 16 months in the control arm, compared with median survival of 4 to 7 months in the other AML studies of older patients suggests that this subset is not truly representative of older AML (e.g., based on exclusion of proliferative AML). In two single-arm trials, decitabine 20 mg/m^2 IV daily for 5 and 10 days achieved CR rates of 24% and 47%, respectively, and overall median survival times of 7.7 months and slightly longer than 1 year, respectively.[20,21] Notably, induction mortalities remained low, and responses also occurred in patients with unfavorable karyotypes, an important difference from low-dose cytarabine. Standard intensive therapy consists of 3 days of an anthracycline with 7 to 10 days of cytarabine 100 to 200 mg/m^2 per dose. Doses should not be attenuated based on age alone. As for younger patients, the choice of anthracycline does not matter as long as the particular agents are used at equitoxic doses. In a large randomized trial, daunorubicin 90 mg/m^2 daily × 3 was compared to daunorubicin 45 mg/m^2 daily × 3 in combination with standard-dose cytarabine. The high-dose daunorubicin arm achieved higher rates of CR, notably after only one course. A survival benefit was seen for patients ages 60 to 65 years.

Investigational treatments are helpful where unfavorable prognostic factors predominate. *Investigational* does not a priori mean low intensity. Patients with an excellent performance status but high-risk disease because of an unfavorable karyotype, preceding MDS, or therapy-related AML may be appropriate candidates for high-intensity programs, whereas low-intensity protocols are indicated for patients with a poor performance status, comorbidities, or those who do not want to undergo intensive chemotherapy. Table 58-4 summarizes the experience with investigational regimens.

Table 58-3 Prognostic Models in Older Patients With Acute Myeloid Leukemia

Model	Predicted Factor	Negative Prognostic Scores
Study Alliance Leukemia	Survival Disease-free survival	CD34 expression >10% WBC >20 ×10^9/L Age >65 yr LDH >700 units/L NPM1 status wild-type*
UK Medical Research Council (UKMRC)	Survival	Adverse cytogenetic group Elevated WBC† Poor performance status† Older age† Secondary AML
Acute Leukemia French Association (ALFA)	Survival	High-risk cytogenetics ± Age ≥75 yr Performance status ≥2 WBC ≥50 × 10^9/L
M.D. Anderson (MDACC)	Remission rate Induction mortality Survival	Age ≥75 yr Secondary AML‡ AHD duration ≥6‡ (12) mo Treatment outside LAFR Unfavorable cytogenetics WBC ≥25 × 10^9/L‡ Hemoglobin ≤8 g/dL‡ Creatinine >1.3 mg/dL Performance status >2 LDH >600 units/L§
Hematopoietic cell transplantation comorbidity index	Early mortality Survival	Dyspnea Coronary artery disease, CHF, MI, or EF <50% Chronic hepatitis, elevation of bilirubin and/or transaminases Cirrhosis Elevations of creatinine, dialysis, renal transplant Secondary AML Depression/anxiety requiring therapy Continued use of antimicrobial therapy after day 0 BMI >35 kg/m^2

AHD, Antecedent hematologic disorder; *AML,* acute myeloid leukemia; *BMI,* body mass index; *CHF,* congestive heart failure; *EF,* ejection fraction; *LAFR,* laminar air flow room (isolation floor); *LDH,* lactic dehydrogenase; *MI,* myocardial infarction; *WBC,* white blood cell count.

§Only significant for prediction of survival.

Table 58-4 Investigational Induction Therapies for Older Patients With Acute Myeloid Leukemia

Drug(s)	N	Median Age (yr) (range)	OR (%)	CR (%)	Median Survival (mo)	Early Mortality (%)
Clofarabine	112	71 (60-88)	46	38	9.8	9.8
Clofarabine + low-dose cytarabine	54	70 (60-82)	67*	63*	11.4	19
Tipifarnib + etoposide	84	77 (70-91)	40	25	5.3	11
Laromustine	85	72 (60-87)	32	23	3.2	14
Idarubicin/cytarabine + lomustine	508	70 (60-86)	68	68†	12.7†	16
High-dose lenalidomide	33	71 (60-88)	30	NA	4	24

CR, Complete remission; *OR*, overall response.
*Significantly higher than with clofarabine alone.
†Significantly higher than with idarubicin plus cytarabine alone.

Patients with a performance status of 3 or 4, severely abnormal organ function, or who are very old (older than 80 years) may be candidates for supportive care because their expected treatment-related mortality is high, and any gains will be minimal with currently available therapies. These decisions are very individual and need to be thoroughly discussed with patients and their families.

Postremission Therapy for Older Patients

To administer repetitive cycles of modest-dose consolidation therapy is a reasonable strategy for patients with good performance status and no adverse cytogenetics. Unlike in younger patients, HiDAC is less effective and, given its higher potential for toxicity in older patients is also less likely to be feasible. There are conflicting data as to the number of postremission cycles (four have been equal to one), the intensity of postremission therapy (one intensive consolidation cycle was better than 1 year of oral maintenance; in another study six cycles of outpatient consolidation were superior to one short but more intense course), and whether or not prolonged maintenance could be beneficial (as suggested in one study).[1] It is expected that the AML genotype will influence the choice of postremission therapy also in older patients, but data are preliminary and require confirmation from larger studies.

HSCT has been hampered by lack of suitable donors and high treatment-related mortality of standard transplant procedures. Reduced-intensity conditioning transplant has opened this treatment modality to a wider range of older patients as demonstrated by a recent analysis showing no significant impact of age on nonrelapse mortality, relapse, disease-free survival, and overall survival. Selection of patients for HSCT would presumably follow guidelines described in younger patients with the caveat that for older patients long-term disease control is more difficult to achieve.

Maintenance Therapy

Whereas most patients achieve CR following induction, only a third maintain it and do not relapse. Some patients will receive an allogeneic HSCT in first remission, but for most, therapy is terminated with completion of the consolidation, and a "watch and wait" strategy is pursued thereafter. To minimize the likelihood of relapse, postconsolidation maintenance therapy strategies have been tried. The graft-versus-leukemia effect following allogeneic HSCT plays a significant role in the reduction of the risk for relapse, and this effect is to a great part mediated by T-cell activation. Therefore nontransplant maintenance strategies have also been aimed at stimulating tumor-specific cytotoxic T lymphocytes and natural killer (NK) cells. Interleukin-2 (IL-2) is a potent effector-activating cytokine with evidence in preclinical models of antileukemic activity. Although at high doses IL-2 was able to induce responses in patients with active disease, the drug-related toxicities precluded these doses, and lower dose schedules have been evaluated instead in patients in CR.[8] None of these studies demonstrated an advantage of low-dose IL-2 maintenance immunotherapy with regard to disease-free and overall survival. An individual patient data metaanalysis from six randomized controlled trials has confirmed this observation. The only study with positive results supplemented IL-2 with histamine dihydrochloride to enhance the function of cytotoxic antileukemic lymphocytes.[22] In this phase III trial, 320 patients with AML and a median age of 57 years were randomly assigned to receive ten 21-day cycles of Il-2 plus histamine dihydrochloride or observation. The results revealed significantly improved 3-year leukemia-free survival (40% versus 26%; $P = .01$) for the treated patients. However, this benefit only included patients who were in their first CR, and overall survival was not affected in either group. Other concepts have been developed based on hypomethylating agents, which are well tolerated and can be administered over longer periods of time. Results are at best inconclusive, including when used after transplant. At this moment, there is no accepted role for maintenance therapy in AML.

Minimal Residual Disease

Minimal residual disease (MRD) remains below the threshold of detection by morphologic and immunohistochemical means. It is estimated that patients in morphologic CR still harbor up to 10^9 leukemic cells, which constitute an important reservoir for later recurrences. Although many of the biologic aspects of MRD remain unknown, the increasingly easy availability of highly sensitive laboratory assays has made the detection of MRD more practical and attractive. Measuring MRD has several advantages: (1) to improve the assessment of the quality of response, (2) to diagnose recurrence earlier, (3) to determine the intensity of postremission therapy, and (4) to prevent a full-blown clinical relapse while still at the level of a molecular relapse. It should be understood that these goals remain theoretical and especially with regard to points 3 and 4 are unproven (with APL as the only exception).

Two techniques are used for the detection of MRD: flow cytometry and reverse-transcriptase polymerase chain reaction (RT-PCR). Flow cytometry is applicable to almost all patients and is based on the identification of an aberrant leukemia immunophenotype. RT-PCR requires identifiable markers such as fusion transcripts (e.g., PML-RARA, RUNX1-RUNX1T1, CBFB-MYH11, DEK-CAN), overexpressed (WT1) or mutated (NPM1, Flt-3) genes. Both assays are comparable in sensitivity, but RT-PCR testing is less specific. Important issues are (1) the threshold of detection that is predictive for relapse; (2) when MRD testing should be done; and (3) if it is predictive for relapse, whether early intervention based on MRD levels is helpful. Different thresholds have been defined in clinical studies, but their validation is lacking. There is some evidence that high levels of MRD following induction are important but that levels at the end of consolidation matter most for overall survival. The only subtype of AML for which MRD measurements are integrated into

clinical decision making in daily clinical practice is APL, which will be addressed in a separate section of this chapter. For all others, implications from MRD testing remain investigational and confined to clinical studies.

Acute Myeloid Leukemia Salvage Therapy

Most patients with AML will require salvage therapy either because they relapsed or because they did not respond to induction therapy (primary refractory). Most relapses occur within the first 2 years following achievement of remission. In an analysis of 1069 consecutive AML patients in first CR who were treated and followed at M.D. Anderson Cancer Center, the yearly risks for treatment failure were 69%, 38%, 17%, 8%, and 7% in the first to fourth year, respectively. With a probability of relapse-free survival of 84% at 6 years for patients who were alive and disease-free at 3 years, it is reasonable to consider patients cured once they have been in CR for at least 3 years. For patients older than 60 years with intermediate-risk cytogenetics, the relapse-free survival was only 56%, indicating that in older patients, a substantial risk for relapse remains even beyond 3 years in remission.

The prognosis for patients in relapse is likely to be guarded, but outcomes are more heterogeneous than the first impression may imply. The two most important predictors for prognosis are the duration of first remission and the number of previous salvage regimens. In a study of 243 patients with AML who have received first salvage therapy, the likelihood of CR was 60% if the duration of the first remission exceeded 1 year and only 19% for patients with shorter remissions. Treatment was not strongly associated with prognosis. Breems et al[23] presented a prognostic score based on a multivariate analysis of 667 patients who were in first relapse. They identified four clinical parameters (duration of first remission, cytogenetics at diagnosis, age at relapse, and previous HSCT or not) and identified three risk groups. In the favorable group, CR was achieved in 85% of patients and overall survival at 5 years was 46%. In the intermediate- and poor-risk groups the numbers for CR were 60% and 34% and for 5-year survival were 18% and 4%, respectively. Prognosis is worse for patients after second salvage, but even then survival expectations at 1 year vary between 2% and 24% depending on a set of clinical variables. In a study of patients with AML who were primary refractory to at least one cycle of HiDAC-based induction therapy, the subsequent CR rate was only 22% with a CR duration of around 9 months and median survival of only 3.8 months.[24]

The goal of salvage therapy is to provide sufficient disease control to allow for an HSCT. Although few patients will be successfully referred for transplantation, outcome is better than with chemotherapy, and 5-year survival expectations following HSCT may vary from 15% (in primary induction failure) to 40% (in secondary remission after first relapse).

There are no standardized salvage chemotherapy regimens. The choice is largely determined by the first remission duration, the patient age, and to a lesser degree the cytogenetics at presentation. Patients with remission durations exceeding 1 year may be successfully reinduced with a regimen similar to the induction. For most patients this means intermediate-dose (1 g/m^2 per dose) or higher-dose (2 to 3 g/m^2 per dose) cytarabine, which is commonly combined with other agents such as anthracyclines and/or fludarabine (e.g., fludarabine, cytarabine [ara-C], idarubicin [FAI]; fludarabine, cytarabine [ara-C], and G-CSF [FLAG]). Mitoxantrone and etoposide are sometimes used, but their efficacy is rather modest and the regimen is associated with severe mucositis. In a recent large international multicenter randomized trial of 326 patients with relapsed and refractory AML, patients received either intermediate-dose cytarabine (1 g/m^2 daily for 5 days) or cytarabine plus clofarabine, a second-generation deoxyadenosine analogue. Although response rates and event-free survival were superior in the combination arm, there was no difference in overall survival. Patients with short remission durations or refractory disease have poor response rates and even worse survival with conventional drugs and are therefore appropriate candidates to participate in clinical trials.

Investigational Therapies

The two most common scenarios in which investigational programs merit serious considerations are situations in which blasts are predictably resistant to therapy and in which patients are unfit for conventional therapy because of age and/or performance status.

Inhibitors of Flt-3

Mutations of the Flt-3 gene are among the most common abnormalities in patients with diploid cytogenetics. ITDs have been associated with high relapse likelihood and worse overall survival. Several inhibitors of Flt-3 have been tested in clinical trials, including lestaurtinib (CEP-701), midostaurin (PKC412), sorafenib (BAY 43-9006), tandutinib (MLN518), semaxanib (SU5416), sunitinib (SU11248), KW-2449, and quizartinib (AC220). Various factors influence the activity of these agents. Blasts with a low mutant allelic burden of Flt-3/ITD may be less dependent on Flt-3 signaling. Whether or not there is an association of the size of the ITD fragment with outcome is controversial. Secretion of Flt-3 ligand is another resistance mechanism under discussion. The spectrum of activity of most of the Flt-3 inhibitors extends to other kinases so that there are differences with regard to specificity between these agents. Also in clinical studies is the anti- Flt-3 monoclonal antibody IMC-EB10, which in preclinical studies showed antiproliferative activity against wild-type and mutant Flt-3 samples.

Single-agent activity for most of the Flt-3 inhibitors is modest, consisting of reductions of circulating or marrow blasts without reaching objective response criteria. The exception has been quizartinib, which achieved CR rates of up to 28% in patients with Flt-3/ITD mutations (13% without) and durable responses in some.[25] Combination therapy of Flt-3 inhibitors with chemotherapy is of larger interest. Although a randomized study of chemotherapy alone versus chemotherapy plus lestaurtinib involving 224 patients in first relapse showed no improvement of response rate or survival, several frontline studies have suggested improved responses in Flt-3/ITD-mutated patients.[26] Large randomized trials in newly diagnosed patients with Flt-3/ITD mutations are under way to validate the benefit of these drugs.

Other Inhibitors of Cellular Signaling Pathways

Cellular signaling pathways control maturation, differentiation, proliferation, apoptosis of marrow blasts, and other crucial cellular processes. Defects in one or several of the signaling cascades in the form of constitutive activation of kinases or dysfunction of adaptor proteins and transcription factors can trigger or propagate the leukemia phenotype. Conversely, many small-molecule targeted drugs are now in clinical trials that aim to abrogate abnormally activated kinases and other enzymes and reverse this process. Compared to the success of tyrosine kinase–inhibitor therapy in chronic myeloid leukemia, the clinical impact of this approach in AML is still limited.

Signaling through Ras/Raf/MEK is activated in many cancers and has been one of the first targets for small-molecule kinase inhibitors. In a phase I study of tipifarnib, a farnesyltransferase inhibitor, in adults with refractory acute leukemias, 29% of patients responded. Later studies proved disappointing with similar survival between tipifarnib and supportive care in older patients with untreated AML. However, a two-gene genetic signature has highlighted subgroups of patients with higher response to tipifarnib, and combination studies with agents such as etoposide appear more promising as well.

Inhibitors of MEK1/2 have demonstrated clinical activity in the salvage therapy for AML. Of 39 patients with relapsed or secondary AML, a third responded if the blasts had mutated KRAS or NRAS, compared with only 8% without mutations of Ras. The study highlights the importance of identifying particular cytogenetic-molecular signatures indicative of increased responsiveness to a specific group of drugs.

Other targets are BCL2 and other antiapoptotic proteins; multidrug resistance proteins; the ubiquitin-proteasome pathway; protein kinase C signaling; aurora kinases, which play an important role in the formation and organization of the mitotic spindle apparatus; the mammalian target of rapamycin (mTOR); and components of the microenvironment (e.g., proangiogenic proteins, cell adhesion molecules).

Epigenetic Therapy

Hypermethylation of CpG-rich islands of DNA together with changes in the conformation of histone proteins (e.g., deacetylation of histone proteins results in tighter packaging of chromosomal material and hence decreased transcriptional activity) lead to suppression of the expression of several genes, some of which function as tumor suppressor genes. In contrast to gene mutations, these epigenetic modifications are not permanent and can be reversed. Two drugs commonly used to affect this change are the DNA methyltransferase (DNMT) inhibitors azacitidine and decitabine ("hypomethylating agents"). Although FDA approved only for patients with MDS, they are widely used for adults with AML within and outside (off label) clinical studies. Because their use is predominantly for older patients with AML, some of the clinical experience has already been addressed.[19-21] Combination trials of DNMT inhibitors with histone deacetylase inhibitors and studies randomizing patients between hypomethylating agents and standard cytotoxic chemotherapy (e.g., decitabine versus low-dose cytarabine) are being conducted.

Gemtuzumab Ozogamicin

GO is a humanized anti-CD33 monoclonal antibody that is chemically linked to a cytotoxic moiety called calicheamicin. Upon binding to CD33, internalization, and dissolution of the link, calicheamicin is released intracellularly and inhibits DNA synthesis, resulting in apoptosis. Three phase II studies evaluated GO in patients with AML in first relapse and demonstrated a CR rate of 16% and a rate for CR without adequate platelet recovery of another 13%, culminating in an overall response rate of 29%. These studies provided the basis for the FDA approval of GO in 2000. Combinations of GO with cytotoxic chemotherapy resulted in hepatic toxicities, namely, venoocclusive disease (sinusoidal obstruction syndrome), that were not observed before. Although this problem was largely resolved by adjusting the GO doses to as low as 3 mg/m^2 in combinations, the expanded spectrum of toxicities plus the observation that GO failed to improve outcome of patients led the FDA to revoke the approval in 2010. However, one large multicenter trial by the MRC has since shown that GO in combination with cytotoxic chemotherapy improves survival in the frontline therapy for patients with favorable cytogenetics.[15] These results were mirrored in a smaller single-center trial in which the combination of FLAG with GO in patients with CBF leukemias resulted in superior event-free survival compared to historical controls of idarubicin plus cytarabine. A trend for better relapse-free survival with GO chemotherapy in patients with favorable cytogenetics was also seen in SWOG study S0106. GO has also been shown to be effective and safe for patients with APL. Identification of niche populations of patients who still derive benefit from GO has led to a resurgence of interest in the drug, which is currently available only through clinical studies.

Novel Cytotoxic Agents

Clofarabine is a second-generation deoxyadenosine nucleoside analogue with substantial structural similarity to its predecessors fludarabine and cladribine. The addition of two halogen molecules provides clofarabine with a more favorable pharmacokinetic profile and distinct spectrum of activity. Clofarabine has been used as single agent and in combination with standard cytotoxic agents (cytarabine, anthracyclines, cyclophosphamide) in patients with both untreated and relapsed/refractory AML. A multicenter study of 112 patients 60 years or older with untreated AML showed a CR rate of 38% with an overall response rate of 46%. Median survival of all patients regardless of response was 9.8 months, and early mortality was 9.8%. Combination studies, including those for younger patients with untreated disease, are under way. Other novel nucleoside analogues such as sapacitabine are in clinical trials.

Laromustine is a novel sulfonylhydrazine alkylating agent with unique properties compared to older alkylators such as BCNU. In an international phase II study laromustine was given as a single IV infusion to patients who were 60 years or older with untreated AML. The CR rate was 23% with an overall response rate of 32%. Early mortality was 14%. Although these patients were older with at least one predefined adverse characteristic at the time of diagnosis, the median overall survival was only 3.2 months. As for other novel cytotoxic drugs, their main use will be in combination treatments, which may require changes in dose and schedules, much of which remains unexplored at the present time.

ACUTE PROMYELOCYTIC LEUKEMIA

APL has unique clinical, pathophysiologic, and therapeutic features. The median age at diagnosis is about 40 years, and it is more frequent in Hispanics and the obese. Despite its rarity (approximately 10% of all AML diagnoses) it is important to promptly diagnose. If managed appropriately APL has the most favorable prognosis of all AMLs. On the other hand, coagulopathies in concert with thrombocytopenia can result in catastrophic bleeding events (especially inside the CNS) with a high early mortality. In 80% of the cases, APL cells are hypergranular with many Auer rods. A microgranular variant (M3v) is often associated with leukocytosis. APL cells are strongly positive MPO staining and lack expression of CD34 and HLA-DR.

APL is almost always the result of translocation t(15;17) that leads to fusion of the gene for retinoic acid receptor alpha (RARA) with the promyelocytic leukemia gene (PML). In very rare cases (<5%) translocation partners other than PML on chromosome 15 result in alternative fusion genes (e.g., PLZF-RARA, NPM-RARA, NuMA-RARA, STAT5-RARA) whose significance lies in possible resistance to all-trans retinoic acid (ATRA). PML-RARA is an abnormal retinoic acid (RA) receptor that represses transcription of a number of RA-activated target genes. It does so mainly by recruiting large protein complexes through the coiled-coil domain of PML, which in turn act as potent transcriptional corepressors. Pharmacologic doses of RA release the corepressors, allow recruitment of coactivators, and thus result in the transcription of previously silenced genes. This leads to a sudden arrest in proliferation and a differentiation response that can be seen in vitro and in vivo within a few days following administration of ATRA (Fig. 58-16). APL is the most dramatic example of the success of differentiating therapy, which has proved disappointing in other forms of AML.

The clinical activity of ATRA was first demonstrated in a study from China, where oral ATRA alone when given over 30 to 90 days achieved CR rates of 85%, an observation that was later confirmed by groups in North America and Europe. ATRA not only achieved high CR rates comparable to chemotherapy alone, but also improved the coagulopathy. ATRA therapy has also been associated in 10% to 25% of patients with the "retinoic acid syndrome" (nowadays referred to as *differentiation syndrome* because it is also seen with other differentiating agents). It occurs within a few days of start of therapy and presents with signs and symptoms resembling capillary leak and respiratory distress syndrome: fever, dyspnea, hypoxemia, pulmonary infiltrates, weight gain, peripheral edema, renal and hepatic dysfunction, and ascites. Differentiation syndrome carries a high mortality unless recognized and managed promptly. Therapy consists of holding the differentiating agent and instituting steroids (e.g., dexamethasone 10 mg for 3 to 5 days with a slow taper over 2 weeks). This intervention will rapidly reverse the manifestations of

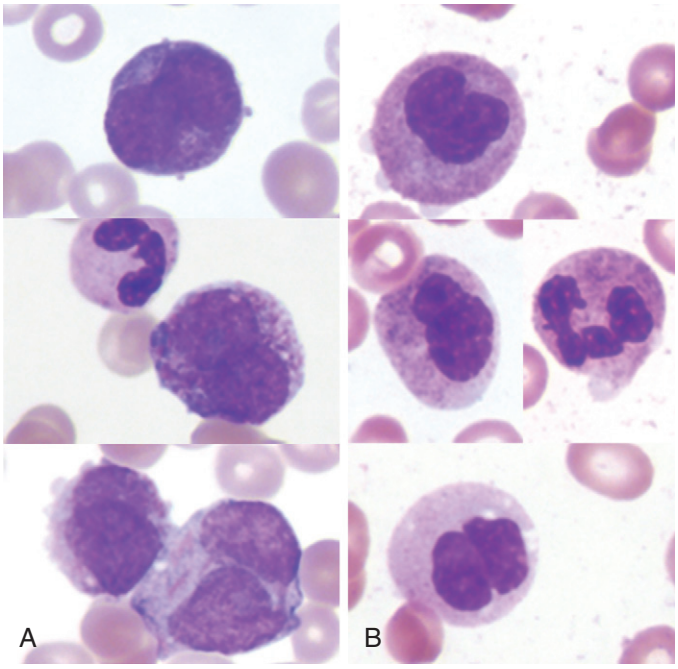

Figure 58-16 Effect of all-trans retinoic acid (ATRA) therapy on acute promyelocytic leukemia (APL) cells. ATRA therapy in APL causes the malignant promyelocytes **(A)** to differentiate, and the effects of differentiation can be seen within days of treatment **(B).** The differentiated APL cells are still somewhat atypical, frequently with bilobed nuclei (compare to normal neutrophil [**B,** *insert center right*]).

differentiation syndrome and has substantially reduced mortality to below 5%. Some investigators have proposed prophylactically using steroids in patients who present with WBC of greater than 10,000/μL.

ATRA alone is insufficient therapy because all patients will eventually relapse. Clinical studies confirmed significantly better disease-free survival for the combination of ATRA plus chemotherapy. In the French APL 93 trial concurrent administration of ATRA with chemotherapy achieved a lower relapse rate at 2 years (6%) compared to sequential administration (16%, $P = .04$) given identical CR rates of 92%. Optimal induction therapy for patients with APL therefore is the combination of ATRA with an anthracycline (daunorubicin or idarubicin). In two large trials from Italy (Italian Group for Haematological Diseases in Adults [GIMEMA]) and Spain (PETHEMA), CR rates were 95% and 89%, respectively, and 2-year disease-free survival was 79%.[27] Sanz et al[27] proposed a risk-stratification model based on WBC and platelet count. High-risk was defined as a WBC of greater than 10,000/μL at diagnosis with significant differences in relapse-free survival between patients with high-, intermediate-, and low-risk disease.

Monitoring response during induction consists of morphologic assessments of blood smears and marrow in addition to serial measurements of PML/RARalpha by RT-PCR assays. The differentiation response of the leukemic blasts may be delayed; therefore repeat marrow studies are not recommended before the blood counts recover at around 4 to 6 weeks of therapy. In some instances a repeat marrow assessment 1 to 2 weeks later may be necessary to establish the response. No early intervention or change of therapy should be undertaken during this time.[28] By the end of induction and with achievement of a morphologic remission, it is very likely that there has also been a complete cytogenetic response. However, molecular testing by RT-PCR is frequently still positive, which at this early point in therapy should not be interpreted as a sign of treatment resistance.

The role of cytarabine during induction and consolidation therapy remains controversial. In two randomized studies of ATRA/anthracycline ± cytarabine from the AML MRC15 trial and the European APL Group, rates for CR and induction failure were comparable, but in the European trial (using daunorubicin as opposed to idarubicin in the MRC trial) the risk for relapse was increased when cytarabine was omitted from the treatment regimen. On the other hand, in the MRC15 trial not only was there no difference in relapse rate, the cytarabine-treated patients experienced a small increase of deaths and higher use of medical resources. In a joint analysis of the European results with those of the PETHEMA group, the benefit of cytarabine was restricted to patients with higher-risk disease. Current recommendations provide an option of using cytarabine in younger patients with WBC of greater than 10,000/μL.

Arsenic trioxide (ATO) has potent antiapoptotic activity in APL cells. Whereas its precise mechanism of action is not well-defined and almost certainly depends on additional mechanisms, it is one of the most active drugs available against APL with high single-agent response rates in relapsed patients. In a study by M.D. Anderson Cancer Center ATRA and ATO were combined in newly diagnosed patients with APL.[29] High-risk patients also received GO. Of 82 patients, 74 achieved CR with an overall response rate of 92%. Among the low-risk group, the CR rate was 95% and no patient relapsed, with an estimated 3-year survival rate of 85% for the whole study group. The combination of ATRA and ATO is currently recommended for patients who are older and/or intolerant to therapy with anthracyclines. Single-agent ATO without ATRA may be particularly attractive where medical resources are scarce and access to cheaper therapies is an economic necessity. In two studies, one from India and one from Iran, single-agent ATO achieved CR rates of close to 85% with 3-year survival rates of 86% (India) and 5-year survival rates of 64% (Iran). Patients with higher-risk disease appeared to respond equally favorably. ATO can cause prolongation of the QTc interval, which may lead rarely to serious cardiac arrhythmias. It is recommended to check an electrocardiogram before each course of therapy and maintain electrolytes such as potassium and magnesium at high-normal levels throughout therapy.

Postremission therapy consists of consolidation and maintenance. Although there remains considerable debate about particular aspects of the consolidation (addition of ATRA, role of ATO, value of cytarabine), the general recommendation is to give another two or three anthracycline-based cycles, typically in conjunction with ATRA because the latter has been shown to reduce relapse risk. There is less agreement on the addition of cytarabine as has already been discussed. ATO in consolidation has been explored in a large randomized U.S. Intergroup study. Addition of ATO to a standard induction and consolidation therapy has significantly improved event-free and disease-free survival. The purpose of consolidation therapy is to convert a morphologic and cytogenetic remission into a durable molecular response. For patients who have achieved a molecular response, maintenance therapy for 1 to 2 years with ATRA ± mercaptopurine and methotrexate has been recommended. Later studies, in particular a large trial by the GIMEMA group, questioned the benefit of ATRA-based maintenance. There are ongoing randomized studies exploring the benefit of maintenance therapy, but it appears likely that the impact of maintenance on overall outcome has changed now that ATRA and ATO are being used earlier during treatment. Whereas maintenance may not be of much use for low-risk patients, it may be considered for high-risk patients who have become molecular responders after consolidation.

RT-PCR testing is essential in the follow-up of patients with APL. In no other leukemia, with the possible exception of chronic myeloid leukemia, does molecular testing play such a critical role and influence clinical decision-making processes. Patients who do not achieve a molecular response by the end of the consolidation (usually 3 months into CR) have a poorer prognosis with a higher likelihood of relapse. Furthermore, these patients have a better survival with early intervention rather than at the time of morphologic relapse. Whereas no further monitoring may be necessary for molecular responders with low-risk disease because of the very low relapse likelihood, monitoring should take place every 3 months for 2 years for patients with high-risk disease, those older than 60 years, and patients for whom treatment delays occurred during consolidation. Positive

PCR test results should be confirmed by a second PCR test within 1 to 4 weeks. If the repeat test results are negative, no further action is necessary; however, close prospective monitoring should be applied.

ATO is effective therapy for patients with relapsed APL, including those with persistent PCR-positive disease. Morphologic remissions are observed in up to 90% and molecular remission in 70% to 80% of patients, respectively.[30] Overall survival at 3 years is between 50% and 70%. Addition of ATRA to ATO may provide little further benefit if ATRA was already part of the induction/consolidation, which is the case most of the time. HSCT should follow achievement of a second remission. Autologous HSCT is recommended for patients who have again achieved a molecular response. For those whose PCR results remain positive despite ATO-based therapy, allogeneic HSCT is another option. CNS involvement at the time of relapse is rare, so that there is no commonly agreed-upon strategy of CNS prophylaxis. Whereas some groups such as the National Comprehensive Cancer Network advocate prophylactic intrathecal therapy for patients in second morphologic remission, the Spanish PETHEMA group showed that two independent risk factors for CNS disease are hyperleukocytosis (WBC >10,000/μL) and occurrence of CNS hemorrhage during induction. Whereas under those circumstances the incidence of CNS involvement has been as high as 5.5%, it was not higher than 1.2% at 5 years for the remainder of the patients.

ADDITIONAL ISSUES IN ACUTE MYELOID LEUKEMIA THERAPY

Hyperleukocytosis

Hyperleukocytosis is defined as a WBC of greater than 100,000/μL (Fig. 58-17). Presumably this should reflect an increase of blasts close to this level although this distinction is not always followed very closely in clinical practice. Myeloid blasts are less deformable than normal myeloid cells and adhere to vessel walls and extramedullary tissues due to a complex array of adhesion molecules, which distinguishes them from lymphoid blasts. Hyperleukocytosis is a medical emergency with a high mortality rate mainly due to pulmonary and CNS complications from bleeding (secondary to anatomic disruption of the endothelial lining of blood cells, DIC, or both) and direct tissue infiltration with inflammatory responses. It is therefore imperative that efforts be undertaken to reduce the blast burden as soon as possible. Because red blood cell transfusions increase the viscosity of blood flow, they should be used judiciously or if possible avoided as long as the WBC remains high. Leukapheresis is a fast and effective method for WBC reduction. Although it has an immediate effect in reducing early mortality, there has been no impact on survival. Leukapheresis does not affect cellular plugs that are already formed in a vascular territory, nor does it affect inflammatory reactions in tissues infiltrated by blasts. Rapid administration of cytotoxic chemotherapy with or without leukapheresis therefore plays an important role. The most effective drug is cytarabine. Hydroxyurea is an oral alternative that is well tolerated and easy to administer. However, hydroxyurea does not effectively infiltrate tissues and thus may not reach extravascular blast infiltrates. Care must be taken to avoid tumor lysis syndrome, using adequate hydration and uricosuric agents, and to meticulously follow electrolyte levels and renal function.

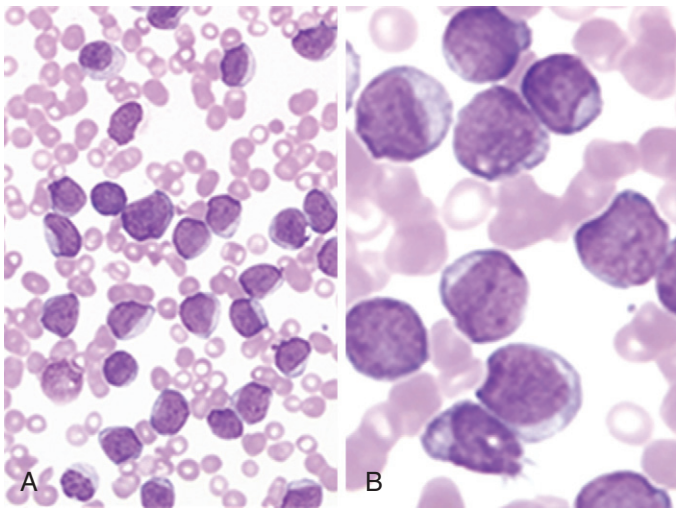

Figure 58-17 HYPERLEUKOCYTOSIS IN ACUTE MYELOID LEUKEMIA. The patient was a 23-year-old man who presented with several weeks of abdominal pain, weight loss, and fatigue. He was found to have a marked leukocytosis of 165,300/μL composed of mostly blasts (**A** and higher-power **B**), which were shown to be myeloblasts by flow immunophenotyping. The patient developed some shortness of breath and hypoxia and underwent two cycles of leukapheresis and hydroxyurea before induction. Molecular analysis revealed the leukemia to have an Flt-3-ITD mutation.

Myeloid Sarcoma

Myeloid sarcoma (granulocytic sarcoma, chloroma) is an extramedullary myeloid tumor composed of myeloid blasts. Myeloid sarcomas can occur in any tissue but most commonly present in the skin, lymph nodes, gastrointestinal tract, testes, CNS, soft tissue, and bones. They can easily be confused with lymphomas and soft tissue sarcomas. Myeloid sarcomas may be isolated; they may occur together with marrow involvement or precede it. In a few instances they may be the relapse manifestation of patients who have been treated for AML in the past. In the context of chronic myeloid malignancies (e.g., MDS, myeloproliferative neoplasms, chronic myeloid leukemia, chronic myelomonocytic leukemia) their appearance represents progression to a blast phase. Myeloid sarcoma even when isolated should be treated systemically with chemotherapy as for any other patient with AML. Radiation therapy may be of help in a few instances to optimize local control. However, in the absence of systemic therapy, subsequent development of systemic AML is very likely. There is controversy over whether patients with myeloid sarcoma do better or worse than those with AML. A recent retrospective comparison between patients with and without isolated myeloid sarcoma and a cohort of AML patients suggests no significant differences in survival and a possible survival benefit with HSCT for all groups.

Central Nervous System Disease

CNS involvement occurs in less than 5% of patients with AML and is therefore much rarer than in ALL. Consequently, there is no role for CNS prophylaxis. Before HiDAC, inv(16) AML was associated with a 30% incidence of CNS leukemia, particularly intracerebral masses. This particular problem has been virtually eliminated with the use of HiDAC but may still be noted in patients with inv(16) AML in whom HiDAC is not delivered. In the presence of symptoms suggestive of CNS disease, further workup should be pursued. Symptoms are due to raised intracranial pressure, mass effect, or infiltration of cranial nerves. Whereas CT scan is a convenient modality to rule out significant anatomic disruptions, it is not very sensitive to detect more subtle signs of leptomeningeal disease, and, if concerns persist, a magnetic resonance imaging scan of the brain (or any other CNS structure where disease is suspected) should be obtained. Lumbar puncture is a crucial component of the workup. Blasts in the cerebrospinal fluid may range from a few cells to several thousand. Treatment consists of intrathecal therapy with cytarabine and/or methotrexate via lumbar route or Ommaya reservoir. The dose of methotrexate should be reduced by 50% if administered into an Ommaya reservoir. A typical schedule includes twice-weekly

intrathecal doses until the cerebrospinal fluid becomes clear. The frequency is then changed to weekly for 2 months, then every other week for 2 months, followed by monthly injections for up to 1 year. Radiation therapy can be a useful alternative, especially in the case of localized lesions such as isolated cranial nerve findings. Although high-dose cytarabine penetrates the blood-brain barrier and may have contributed to a lower rate of CNS involvement over the years, it by itself is not sufficient therapy once there is CNS disease. The risk for CNS involvement is higher in AML with any type of monoblastic differentiation and those cases with a high WBC (>100,000/μL) at presentation. Although some authorities have recommended routine screening for CNS disease in these patients, this is not common practice.

Pregnancy

AML diagnosis is a rare event during pregnancy. In a case-control study of 785 women with AML ages 15 to 50 years compared with 1576 age- and sex-matched controls, AML occurred at a rate of 1.3% in the pregnant group and 3.4% in the control group, resulting in an odds ratio of 0.44 in favor of the women who were pregnant. The response to treatment is not affected by pregnancy. AML therapy during the first trimester is problematic due to the toxic and teratogenic effects of chemotherapy on the fetus. Under those circumstances, termination of pregnancy before institution of induction therapy should be strongly considered. Pregnancy outcome during the second and third trimester is much more favorable, in which successful treatment of the AML and delivery of normal infants have been reported. Daunorubicin may be preferable over idarubicin because the latter is more lipophilic and has a higher DNA affinity, raising the specter of higher maternal-fetal transfer and toxicity to the fetus.[1] It is not advisable to delay therapy once the diagnosis of AML is made given the high risk for maternal death. In situations where the leukemia behaves indolently and women are close to delivery, a conservative approach can be chosen with supportive care and induction of labor as soon as possible. These decisions are based on clinical judgment and discussion with the patient.

FUTURE DIRECTIONS

The backbone of AML therapy has not changed substantially in the previous three decades and is heavily dependent on cytarabine in combination with other cytotoxic chemotherapy. Molecular signatures and identification of signaling pathways that are abnormally activated or regulated in AML blasts are contributing to a more complex picture of the biology of AML, provide more accurate prognostic information, and ultimately offer targets for drug development.

CHAPTER 59

MYELODYSPLASTIC SYNDROMES: BIOLOGY AND TREATMENT

Daniel J. DeAngelo and Richard M. Stone

Over the past several decades, many terms have been used to describe the bone marrow (BM) failure syndromes, which often terminate in an overt acute leukemia. The terms include refractory anemia (RA), preleukemia, smoldering acute leukemia, oligoblastic leukemia, refractory dysmyelopoietic anemia, and myelodysplastic syndrome.[1-5] Patients typically present with varying degrees of anemia, leukopenia, and thrombocytopenia, rendering many transfusion dependent or susceptible to infection or hemorrhage. The term *myelodysplastic syndrome* (MDS) is the currently accepted norm that is used to describe this clinical entity. MDS may arise either de novo or secondary to ionizing radiation, toxins, or chemotherapeutic drug exposure.[6-11] The natural history of these syndromes ranges from an acute precipitous decline over several weeks to a chronic condition that lasts many years. The actual incidence of MDS is unknown. Unfortunately, the incidence rates of MDS were not reported to the National Cancer Institute's Surveillance Epidemiology and End Results (SEER) Program until 2001. Estimates in Europe range from 3 to 20 cases per 100,000, but in the United States, more than 10,000 new cases are diagnosed each year (median age, 76 years).[12-14] The incidence in men is significantly higher than in women (4.5 vs. 2.7 per 100,000). MDS is rarely seen in patients younger than age 50 years but rapidly increases with advancing age and may equal the incidence of acute myeloid leukemia (AML) by the eighth decade of life.[15-17] For example, the age-specific incidence rates of MDS are approximately 5 per 100,000 for ages 60 to 69 years, but increase to approximately 50 per 100,000 for ages 70 to 79 years.[18]

The various pathologic entities of MDS previously were classified by the French-American-British (FAB) Cooperative Group into five subtypes based on a set of criteria that included BM morphology and the percentage of myeloblasts,[19] with the presence of greater than 30% myeloblasts classified as AML. The FAB classification scheme, based largely on the histologic changes within the BM, has been extremely useful in assessing prognosis in patients with MDS, but the arbitrary division between MDS and AML based on the presence or absence of 30% myeloblasts is biologically inconsistent. In large studies, patients with refractory anemia with excess blasts in transformation (RAEB-T) and AML have similar outcomes. As a result, the World Health Organization (WHO) has adopted the definition of AML in a patient with 20% or greater myeloblasts and have removed the antiquated term RAEB-T.[20]

Most patients with MDS have progressive cytopenias, and a large fraction of patients eventually develop overt AML.[21] Patients with secondary AML from an underlying MDS typically are treated with multiagent chemotherapy in an attempt to delete the leukemic clone.[22] Nevertheless, the same problems exist as with MDS: advanced age, therapy-related toxicity, and resistant disease. Stem cell transplantation (SCT) remains the best chance for cure, but this strategy is not appropriate for the majority of patients because of their advanced age. Treatment of MDS ultimately is intended to extend overall survival by both improving the peripheral blood cytopenias and delaying the leukemic transformation. However, the more immediate goal of therapy is to relieve symptoms and improve the quality of life while minimizing side effects.

BIOLOGY

Pathogenesis

Myelodysplasia is the result of a transformation of a myeloid stem cell. A hematopoietic stem cell (HSC) is capable of self-renewal and can give rise to more differentiated progeny.[23-26] As the stem cell differentiates, it becomes lineage specific. An early pluripotent stem cell can give rise to both lymphoid and myeloid cells. However, the neoplastic transformation of the myeloid stem cell is the initial event that leads to myelodysplasia.[27] MDS rarely transforms into acute lymphocytic leukemia, thus suggesting that the MDS myeloid stem cell has lost its lymphopoietic potential.[28,29] A poorly defined transforming event(s) affects the pluripotent myeloid stem cell in MDS, thus conferring a growth advantage that eventually leads to development of monoclonal hematopoietic progeny. Many genetic mutations regulate this process, and these alterations determine both the biology and clinical aspects of the disease.[30]

The clinical hallmark of patients with myelodysplasia is the development of ineffective hematopoiesis (Fig. 59-1). Interestingly, cellular turnover within the BM often is increased in most patients with myelodysplasia.[31] Cell kinetic studies have revealed a dramatic increase in the rate of cell division. The peripheral cytopenias are thought to be secondary to an increase in apoptosis, or programmed cell death, resulting in a futile increase in cell cycling.[32,33] Impaired cellular function is another important clinical feature of myelodysplasia. Erythroid precursors have a decreased response to erythropoietin (EPO), which may contribute to subsequent anemia.[34] In addition, terminally differentiated cells in MDS have functional defects. Mature granulocytes have decreased myeloperoxidase activity,[35-37] and platelets may have impaired aggregation properties.[38] The oncogenic pathway is not a single-step process. Sequential genetic changes are required to change a transformed myelodysplastic stem cell into a true neoplasm that often leads to development of AML.[39]

Myelodysplastic syndrome is a clonal hematopoietic disorder.[40] BM cytogenetic analysis has been a great asset in the evaluation of the clonal nature of the MDS stem cell.[41-43] The clonal nature of MDS has been best elucidated by the use of X-inactivation studies.[44,45] These studies use restriction fragment length polymorphism (RFLP) analysis to study the differences between the methylation patterns of inactive versus active X chromosomes. RFLP analysis using the phosphoglycerate kinase and hypoxanthine phosphoribosyltransferase genes as well as the polymorphic genes of glucose-6-phosphate dehydrogenase all have demonstrated clonal hematopoiesis within the granulocyte, monocytic, erythroid, and megakaryocytic lineages in patients with MDS.

Apoptosis

Programmed cell death, referred to as apoptosis, is an important and active cellular process that regulates cell and lineage population.[46] The rate of apoptosis is finely regulated by the ratio of proapoptotic

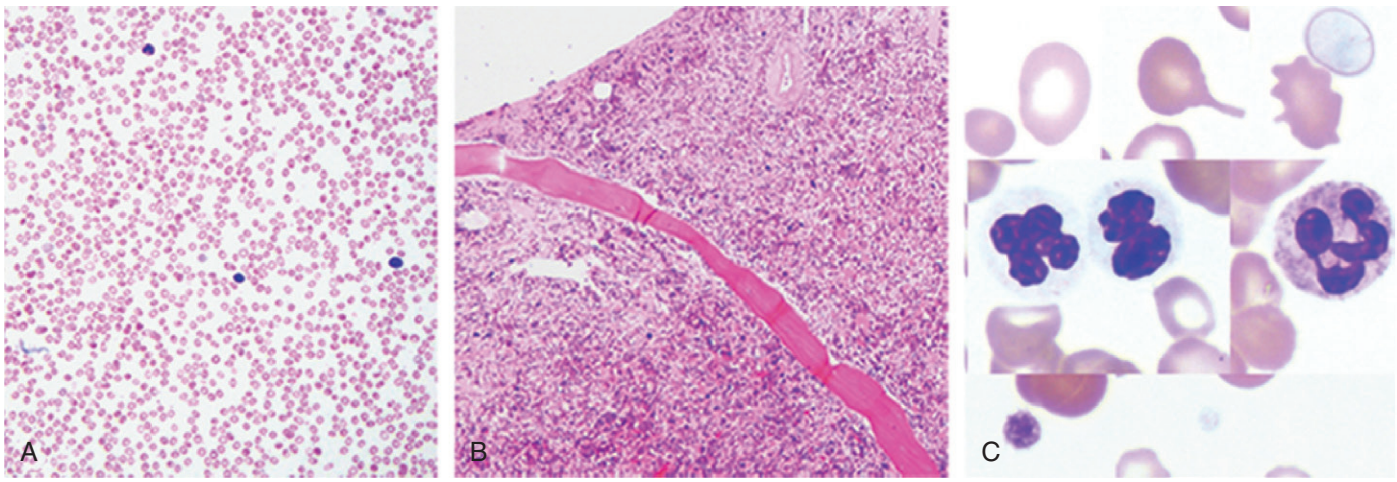

Figure 59-1 ELEMENTS OF MYELODYSPLASTIC SYNDROME. Myelodysplastic syndromes are generally characterized by cytopenias **(A)** caused by ineffective hematopoiesis **(B),** which is related to multilineage dysplasia **(C). A,** This patient presented with a white blood cell count of 1500/μL, hemoglobin 8.9 g/dL, and platelet count 47,000/μL. **B,** The bone marrow was hypercellular, indicating ineffective hematopoiesis. **C,** Evidence of trilineage dysplasia was apparent on the peripheral smear. Anisocytosis with macro-ovalocytes and poikilocytosis is seen in the red blood cells (**C,** *top*). The latter included the somewhat uncommon finding of Cabot ring forms *(right).* A large proportion of the granulocytes were severely hypogranular (**C,** *middle left*) compared to some normal forms still in the circulation *(right).* Platelets (**C,** *bottom*) were decreased in number, and many were severely hypogranular (*middle,* barely visible) compared with residual normal platelets *(left).*

proteins, such as c-Myc, p53, Bax, and Bad, to the antiapoptotic proteins, which include Bcl-2 and Bcl-XL.[47-50] Increased apoptosis has been documented within $CD34^+$ BM cells in patients with MDS.[51] This increased apoptosis seems to be highest in patients with RA compared with those with RAEB and may account for the cytopenias that are the hallmark of early-stage MDS.[52-55] For example, the intracellular ratio of c-Myc to Bcl-2 is higher in $CD34^+$ cells in patients with MDS compared with those from normal patients or patients with AML.[56] In addition, an increased level of apoptosis is associated with increased levels of inhibitory cytokines, such as tumor necrosis factor-α (TNF-α).[57] TNF-α is increased across all MDS subtypes and may inhibit the development and maturation of the hematopoietic precursors. TNF-α may increase the production and secretion of other proapoptotic cytokines, such as interleukin-8 (IL-6), transforming growth factor β, interferon-γ, and Fas ligand. Use of growth factors, such as erythropoiesis-stimulating agents (ESAs) and granulocyte colony-stimulating factor (G-CSF), has been shown to decrease the rate of apoptosis in some patients.[58-60] These findings suggest that increased levels of apoptosis is associated with early-stage MDS, but decreased levels of apoptosis may help propagate the transformation from MDS to AML.[52,54,61-63]

Hematopoiesis

The colony-forming capacities of the pluripotent HSCs and their progeny are low or absent in many patients with MDS.[64] The BM cells as well as peripheral T cells from patients with MDS seem to produce lower levels of granulocyte-macrophage colony-stimulating factor (GM-CSF), IL-3, macrophage colony-stimulating factor (M-CSF), and IL-6. The colony-forming unit granulocyte-macrophage (CFU-GM) is less responsive to both G-CSF and GM-CSF in patients with MDS.[65,66] These findings are more dramatic in patients with the higher grade MDS. In addition, the erythroid progenitor cell, burst-forming unit-erythroid (BFU-E), is less responsive to EPO in vitro.[64] There also seems to be a direct correlation between the size of the BFU-E and the EPO level in patients with MDS. These findings may help explain the peripheral blood cytopenias in patients with MDS and the observation that additional EPO is of limited clinical benefit.

Epigenetic

Epigenetics is the alteration of gene expression without altering the primary DNA sequence.[67-70] These modifications can occur at multiple levels, the most common involving DNA methylation. DNA methylation involves the addition of methyl groups to a cytosine residue.[71-73] Cytosine methylation typically occurs when a cytosine is followed by a guanine in the so-called CpG pair. CpG pairs are underrepresented within the human genome, but when they do occur, they occur clustered in so-called CpG islands. These CpG islands typically are located proximal to gene promoter regions and regulate gene expression.[74,75] For example, methylation of CpG islands is associated with gene silencing. The process of gene silencing may be physiologic in the case of both imprinted genes as well as regulating gene dosage of genes on the X chromosome in females.[67] Tumor suppressor genes are thought to undergo this aberrant gene silencing mechanism, leading to abnormal physiologic consequences.

Epigenetic changes in MDS and AML have become increasingly important. For example, the promoter methylation of the α-catenin gene *CTNNA1* may be an important underlying abnormality involving the loss of chromosome 5.[76] Other examples include promoter methylation of the p15INK4B gene.[72,77,78] This gene often is hypermethylated in patients with therapy-related MDS or therapy-related AML. In addition, methylation changes of this gene are seen more frequently in patients with loss of chromosome 7 and in patients who progress from RA to RAEB.[78]

Genetic Pathways Involved in Disease Progression

The genetic changes that occur in patients who transform from MDS to AML are numerous, complicated, and involve a multistep process characterized by activation of specific oncogenes as well as inactivation of tumor suppressor genes.[39] RAS mutations are frequently identified in patients with hematologic malignancies.[79-81] In patients with MDS, RAS was mutated in as many as one-third of the cases, with the highest frequency in patients with chronic myelomonocytic leukemia (CMML).[82] The FMS oncogene encodes for M-CSF and, similar to RAS, is most preferentially seen in patients with CMML.

Mutations involving the p53 tumor suppressor gene on chromosome 17p is rarely identified in patients with MDS, but when seen, they often correspond with disease progression and resistance to chemotherapy.[83,84] Although the FMS-like tyrosine receptor III (FLT-3) is the most common single mutated gene in patients with AML, it is mutated in fewer than 3% of patients with MDS.[85-88]

Most patients develop genetic alterations that include the gain or loss of part or whole chromosomes as well as specific gene mutations and promoter methylation changes.[89] For example, patients with abnormalities involving chromosome 5 and 7 often acquire additional mutations in p53, RAS, or both, followed by promoter methylation changes of p15.[87,90] This process often is involved in patients with therapy-related MDS who previously received alkylating agent therapy and typically occurs 3 to 5 years after chemotherapy exposure.[88]

Genetic mutations that are commonly seen in patients who previously received a topoisomerase II inhibitor, such as the anthracycline doxorubicin, involve the complex acquisition of chromosomal translocations often involving the mixed lineage leukemia (MLL) gene on 11q23.[91-101] More than 30 different translocations have been identified that involve 11q23, and they account for approximately 5% of all translocations that occur in acute leukemia. Reciprocal translocations involving the 11q23 gene have been described in patients with acute lymphoblastic leukemia (ALL), AML, acute biphenotypic leukemia, and MDS. Other chromosomal translocations that are seen less commonly after anthracycline exposure include the AML1 gene on 21q22 often leading to translocation of t(3;21),[91] the core-binding factor β (CBF-β) gene on chromosome 16 leading to inversion of chromosome 16 [inv(16)],[92] and the retinoic acid receptor α (RAR-α) gene on chromosome 17 characterized by translocation t(15;17) and development of acute promyelocytic leukemia.[93-95] In addition, mutations of the NUP98 gene on chromosome 11p15 have been associated with exposure to topoisomerase II inhibitors.[96,97] These cytogenetic changes characterized by specific chromosomal abnormalities, with the notable exception of NUP98 on 11p15, subsequently develop RAS, BRAF, c-KIT, or FLT-3 mutations followed by changes in the methylation pattern within the p15 promoter.[98,99]

Patients with a normal cytogenetic karyotype or other nonspecific chromosomal abnormalities often evolve from an MDS to an AML phenotype with a different and distinct process. These patients typically develop acquisition of a RAS mutation or another mutation involving a transcription factor,[100] which are known as class II mutations, or mutations involving tyrosine kinases, which are known as class I mutations. Examples of class I mutations include FLT-3, c-KIT, c-FMS, and JAK2.[101,102] Also included are genes further downstream within the RAS-BRAF-MEK-ERK pathway. They include N-RAS, K-RAS, BRAF, and PTPN11. This class of mutations results in the constitutive activation of the cell cycle leading to an increase in cell proliferation. For example, whereas mutations in RAS are commonly seen in monocytic subtypes of AML and in CMML, PTPN11 genes are commonly mutated in juvenile myelomonocytic leukemia.[103,104] The class I mutations are considered "late events" in the pathogenesis of leukemia but are thought to cooperate to a high degree with class II mutations. Examples of class II mutations that can be seen in patients who transform from MDS to AML include CCAAT enhancer-binding protein α (CEBPα), AML1, and rarely internal tandem duplications of MLL (MLL-PTD).[105-107]

As expected, patients with de novo and therapy-related MDS and AML have heterogeneous clinical presentations but often have similar cytogenetic abnormalities.[89,108,109] Although three distinct cytogenetic subgroups can be identified (chromosome 5/7, MLL gene on 11q23, and normal karyotype), many different genetic pathways have been outlined for patients with therapy-related MDS and therapy-related AML. Some of these changes are more consistent with the clinical presentation of MDS (e.g., –5/5q– or –7/7q–), but other abnormalities are more often related to the presentation of overt AML [e.g., translocations involving 11q23, inv(16), and t(15;17)]. However, the frequent association of both class I and II mutations argues strongly for their cooperative nature in the development of MDS and AML.[110]

DIFFERENTIAL DIAGNOSIS

Before a diagnosis of MDS can be made, it is important to consider alternative diagnoses, especially if the patient is younger than 50 years (Table 59-1). Although most patients with MDS have normal or hypercellular BM, approximately 10% to 15% of patients have hypocellular BM that may be difficult to distinguish from aplastic anemia.[111] The presence of a clonal chromosomal abnormality will confirm the diagnosis of MDS.[112] In addition, patients with aplastic anemia typically have greater TNF receptor expression than do patients with MDS.[113] It is important to rule out the diagnosis of paroxysmal nocturnal hemoglobinuria (PNH).[114] Patients with hypocellular MDS have a clinical presentation similar to patients with aplastic anemia and have a better overall prognosis compared with other patients with MDS, especially those who respond to immunosuppressive therapy.[115,116]

Similarly, the presence of myelofibrosis may make adequate assessment of the BM aspirate difficult.[117,118] Patients with significant fibrosis within the BM cavity often have an unaspiratable or aspicular aspirate specimen. Therefore, the ability to analyze the BM aspirate for dysplastic features is markedly limited. However, in some patients, the diagnosis of myelodysplasia can be easily made, and the BM biopsy shows an increased number of reticulin fibers.[119] Reticulin stain, typically by silver impregnation, is an important method for identifying underlying BM fibrosis but should be distinguished from marked collagen fibrosis, which is often seen in patients with chronic idiopathic myelofibrosis (agnogenic myeloid metaplasia with myelofibrosis). Extensive mature collagen fibrosis can be demonstrated by trichrome stain and is extremely uncommon in patients with MDS. Although BM fibrosis can be seen in all subtypes of MDS, it is more

Paroxysmal nocturnal hemoglobinuria

frequent in CMML and therapy-related MDS.[120] Patients with MDS and fibrosis can be distinguished from patients with chronic idiopathic myelofibrosis.[121] The latter entity is associated with marked splenomegaly, an unusual feature in patients with MDS regardless of the degree of BM fibrosis. The absence of splenomegaly and an unusually rapid progressive clinical course helps distinguish patients between MDS and chronic idiopathic myelofibrosis, which usually is more indolent. Other disorders to consider in cases of extensive fibrosis include chronic myeloid leukemia (CML), especially accelerated phase disease, and acute megakaryocytic leukemia (FAB-M7).[122]

Variants of CML as well as atypical CML can be difficult to distinguish from CMML.[123] The WHO currently lists CMML in its own category; therefore, it is no longer considered part of the MDS.[20] Nevertheless, the differential is important. CML is distinguished by the presence or absence of a *BCR-ABL1* fusion gene.[124] The term *atypical CML* represents a diffuse group of disorders that are BCR negative.[125] Their clinical prognosis is somewhat worse than in patients with BCR-ABL given the inability to target a tyrosine kinase. Patients with atypical CML often have a short overall survival time and poor response to therapy. Clinically, they can be distinguished from patients with other forms of MDS by an increase in basophilia and progressive leukocytosis as well as organomegaly, specifically splenomegaly.[126] These patients typically have marked thrombocytopenia and eventually develop BM failure without transformation to AML. In a review of 76 BCR-negative patients from the MD Anderson Cancer Center, the median overall survival was 24 months, with AML transformation in 8 patients. Chromosomal abnormalities were seen in 30% of patients, with trisomy 8 the most common abnormality identified. Patients with atypical CML can be difficult to separate clinically and pathologically from patients with MDS or other myeloproliferative disorders.

Dysplastic hematopoiesis is a common finding accompanying human immunodeficiency virus (HIV) infection.[127,128] An HIV serologic test must be obtained to exclude HIV infection, especially in patients with high-risk lifestyles, as well as young patients. The typical BM aspirate and biopsy findings in patients with HIV infection include a hypercellular BM and evidence of trilineage dysplasia, which is most predominant within the erythroid lineage.[129,130] The erythroid hematopoiesis almost always is megaloblastic, and reticulated fibrosis is often seen in BM biopsies. Most patients have polyclonal plasma cell expansion, and lymphoid aggregates and granulomas are often seen. The differential diagnosis of erythrodysplasia in patients with HIV infection includes medications, opportunistic infections, or a direct effect of HIV on the hematopoietic progenitor cells. These findings reaffirm the need for serologic screening for HIV in patients with unexplained cytopenias.

A number of drugs can cause erythrodysplasia and complicate the evaluation and diagnosis of a patient with cytopenias. These medications include valproic acid,[131] mycophenolate mofetil,[132] ganciclovir,[132,133] alemtuzumab,[134] nucleoside analogues such as fludarabine and cytarabine, and the antimetabolites mercaptopurine and methotrexate. The BM changes associated with these medications include macrocytic anemia, reduced neutrophil lobation, and frank neutropenia and thrombocytopenia. In fact, some patients may have trilineage dysplasia, making an accurate diagnosis difficult.

Nutritional deficiencies must be excluded in any patients in whom the diagnosis of MDS is being entertained. These include vitamin B_{12} and folate deficiency[135] and copper deficiency.[136,137] Copper deficiency in adult patients is rare but can occur after gastrectomy, prolonged parenteral nutrition, or even enteral feeding if copper is not included in the formulation. Rarely, copper deficiency develops after ingestion of large amounts of zinc supplements because zinc excess results in concomitant copper deficiency. Clinically, patients with copper deficiency present with signs and symptoms of profound anemia. In addition, copper deficiency may cause a variety of neurologic complications, including central nervous system demyelination, peripheral neuropathy, myelopathy, and even optic neuritis. In patients with severe cooper deficiency, hemoglobin levels may fall as low as 3.5 g/dL. The mean corpuscular volume (MCV) often is normal or slightly increased, and the red blood cells (RBCs) on the peripheral smear are hypochromic and microcytic. Patients typically present with mild neutropenia with neutrophil counts of 1000/mL. BM examination will reveal a cellular BM with early erythroid vacuolization and moderate numbers of ringed sideroblasts.

A number of drugs may induce sideroblastic anemia, including isoniazid[138] and chloramphenicol.[139,140] Cycloserine and pyrazinamide also have been implicated in rare cases. With isoniazid, the anemia is modest, with hematocrits typically in the 26% range, low MCV, and dimorphic RBC morphology. Abundant ringed sideroblasts are present within the BM, and typically the anemia is rapidly reversed with discontinuation of the offending agent. However, administration of large doses of pyridoxine up to 200 mg/day may accelerate reversal of the anemia.

Although chloramphenicol typically produces a ringed sideroblastic anemia, an idiosyncratic BM failure syndrome associated with chronic administration also can be seen. When this occurs, a prominent feature within the BM is vacuolization, specifically of the early erythroid precursors. Patients often have marked reticulocytopenia and increased serum iron levels. In most cases, the anemia is reversed with discontinuation of the drug; however, some patients may have profound, long-lasting evidence of BM failure.

Sideroblastic anemia is associated with alcoholism with or without folate and vitamin B_{12} deficiency.[141] As many as one-third of patients who have chronic alcoholism may have sideroblastic changes within the BM, including dimorphic erythroid cells. Patients often have a markedly elevated MCV, which is impressively uniform. The ringed sideroblasts often disappear within days to weeks after discontinuation of alcohol intake.[142] However, concurrent vitamin deficiencies or liver disease may further affect the peripheral blood cytopenias and, importantly, the recovery phase.

CLINICAL FINDINGS IN PATIENTS WITH MYELODYSPLASTIC SYNDROMES

Erythroid Cells

The diagnosis of myelodysplasia in patients with anemia, neutropenia, thrombocytopenia, or a combination thereof depends on the demonstration of dysmorphic features within the BM (Table 59-2 and Fig. 59-2). Both a BM aspirate and a biopsy should be obtained. An aspirate usually can assess cellular morphology and quantitation of myeloblasts, but accurate assessment of BM cellularity and localization of immature precursors require a review of the biopsy sections. Occasionally, multiple sampling is required to make a definitive diagnosis because the affected BM is distributed unevenly or the patient develops progressive dysplastic features over time.

Almost all patients with MDS (>90%) present with fatigue and lethargy, which is associated with chronic anemia.[143] The anemia most often is macrocytic, with a significantly reduced reticulocyte index. The most recognized morphologic abnormality of the RBCs on examination of the peripheral blood smear consists of oval macrocytes; however, in rare cases, teardrop cells or dacrocytes, elliptocytes, and acanthocytes are seen.[144] It remains essential to exclude other causes of macrocytic anemia in this population, including vitamin B_{12} and folate deficiency.[145] The anemia in patients with MDS is a result of ineffective erythropoiesis. EPO levels usually are normal or elevated.[3,146] In addition, most patients have evidence of abnormal iron utilization. Other patients have evidence of increased fetal hemoglobin synthesis,[147] abnormal RBC antigens,[148] increased RBC fragility, and low levels of pyruvate kinase. The latter two abnormalities may result in an abnormal Ham test result secondary to increased hemolysis.[149]

It is important to exclude the diagnosis of PNH even in patients without a history of thromboembolic disorders. The most efficient test is the absence of polyinositol glycol–associated antigens by flow cytometric analysis because of the absence of the PIG-A gene. PNH

Flow cytometry (not useful for quantitation)

is diagnosed by the absence of CD55 and CD59 on RBCs and the absence of CD11b on monocytes.[150,151] Some patients have a small clone of PNH cells, but this finding is of unclear clinical significance.[152,153] Other possible features of MDS include disordered α- and β-globin chain synthesis[154,155] and hemoglobin H inclusions.[156]

Morphologic features within the BM aspirate include megaloblastic erythroid precursors, often with multiple nuclei or asynchronous maturation of the nucleus and cytoplasm. Occasionally, ringed sideroblasts, which are RBC precursors with iron-laden mitochondria, can be identified (see Fig. 59-2).[157] Ringed sideroblasts are defined by the presence of at least five Prussian blue—staining iron granules encircling more than one-third of the nucleus of an erythroblast. The presence of ringed sideroblasts without morphologic features of dysplasia also can be seen in unrelated congenital and malignant hematologic conditions. RA and refractory cytopenia with multilineage dysplasia (RCMD) typically are differentiated from refractory anemia with ringed sideroblasts (RARS) and refractory cytopenia with multilineage dysplasia and ringed sideroblasts (RCMD-S) by the presence of greater than 15% ringed sideroblasts.[158]

One unusual feature of the FAB or WHO classification scheme occurs when greater than 50% of the total cellularity is composed of erythroid precursors.[19] In this case, if greater than 30% of the nonerythroid cells are myeloblasts, a diagnosis of erythroleukemia is made (FAB-M6A,or WHO AML, NOS, acute erythroid leukemia, erythroid/myeloid type). This differs from the pure erythroleukemia described by Deguglielmo (FAB-M6B).

Myeloid Cells

A large proportion of patients, approximately 50%, with MDS either present with neutropenia or develop neutropenia as a result of disease progression.[159] Not only is MDS associated with a quantitative neutrophil defect but also with qualitative defects. Patients with MDS often have a reduced inflammatory response to infections. Patients with MDS have diminished production of many hematopoietic growth factors, and these likely account for the qualitative neutrophil defects and their reduced phagocytic properties. Despite this, recurrent infections occur in only 10% of patients,[160] but this is the cause of death in approximately one-fifth of the patients with MDS.[161]

The most common infections in patients with MDS are bacterial, usually from the lower respiratory tract, skin, or perineal area. Recurrent infections can occur even in the absence of severe neutropenia, likely from granulocyte functional impairment. In patients with CMML,[162,163] the monocytes are also derived from defective HSCs and similar qualitative defects in terms of cell adhesion and phagocytic and cell killing properties leading to an increased rate of infections.

Abnormalities of the myeloid series range from subtle to rather striking (Fig. 59-3).[19] They include a left shift toward more immature forms, even without an excess of myeloblasts. The myeloid precursors also may show asynchronous maturation of the nucleus and cytoplasm as manifested by a lack of granule formation. The nucleocytoplasmic dyssynchrony is most clearly represented in the early myeloid cells, or *abnormal promyelocytes*. Their granular cytoplasm, reticulated nucleus, and prominent Golgi apparatus characterize these dysplastic promyelocytes. The more mature granulocytes often are hypogranulated and may be hypolobated as well. Granulocytes with a bilobed nuclear structure are referred to as pseudo–Pelger-Huet cells.[164] There is a congenital abnormality in pediatric patients in which all of the neutrophils are bilobed or hyposegmented; this is termed the *Pelger-Huet anomaly,* which is a benign condition.

The most critical finding in patients with MDS is the presence and quantification of the myeloblasts. The absolute proportion of myeloblasts reflects the defect in the differentiation capacity of the abnormal HSC and represents the most important prognostic finding. The diagnosis of AML is established if there are more than 20% myeloblasts based on the WHO classification scheme or greater than 30% based on the older FAB criteria.[19,20] Quantification of myeloblasts should be performed on a cellular and spicular BM aspirate and not by flow cytometric analysis because the latter can be affected by peripheral blood dilution of the sample.

Megakaryocytes

Thrombocytopenia is present in approximately half of patients with MDS and may represent the only cytopenia in 5% of cases.[165] The finding of thrombocytosis is uncommon and typically associated with either the 5q syndrome[166] or a JAK2 mutation, as is the case in patients with refractory anemia with ringed sideroblasts and thrombocytosis (RARS-T).[167] As in the case with neutrophils, patients with MDS often have both a quantitative as well as a qualitative defect with their platelets.[38] The latter can be identified by careful examination of the peripheral blood smear, on which giant or agranular platelets often are identified. Upon examination of the BM, the megakaryocytes often are small or micromegakaryocytic and contain fewer nuclear lobes (hypolobated) than their normal counterparts (Fig. 59-4).[19,164,168] In patients with the 5q syndrome, the megakaryocytes are nonlobated and mononuclear.[166]

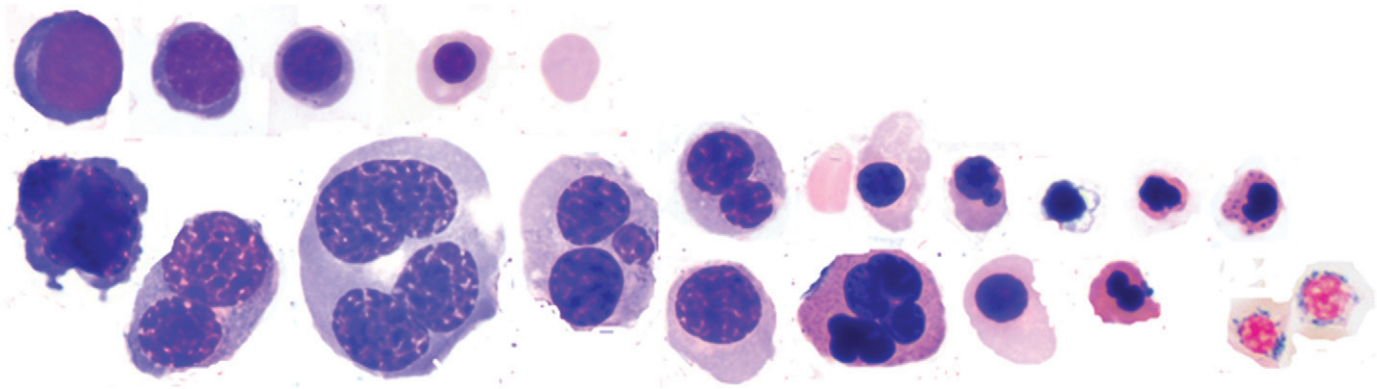

Figure 59-2 ERYTHROID DYSPLASIA. Examples of dysplastic erythroid precursors *(bottom)* compared to those with normal morphology in the sequence of erythroid maturation *(top)*. The dysplastic forms include (*left* to *right*) abnormal immature forms with multinucleation; maturing forms with multinucleation and nuclear-to-cytoplasmic dyssynchrony; and more mature forms with megaloblastoid change, nuclear budding, cloverleaf forms, cytoplasmic vacuolization, and cytoplasmic stippling. Ringed sideroblasts *(far right)* also are evidence of erythroid dysplasia. Photomicrographs are from patients with refractory cytopenia with multilineage dysplasia and ringed sideroblasts.

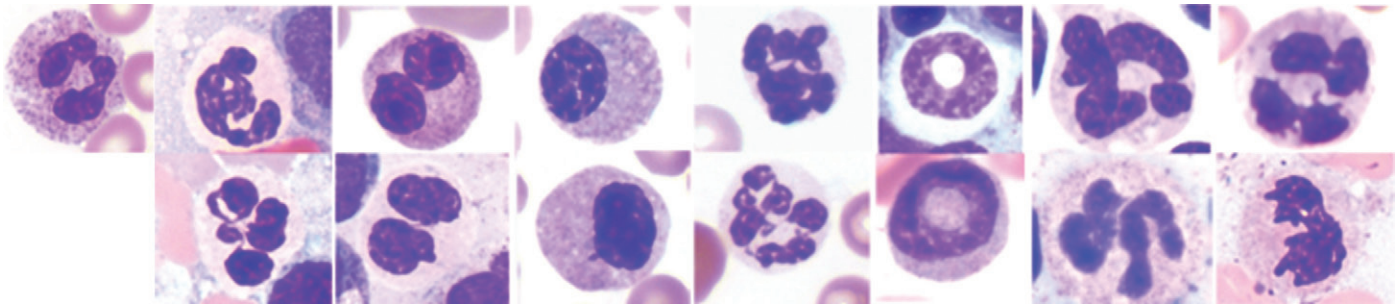

Figure 59-3 GRANULOCYTIC DYSPLASIA. Granulocytic dysplasia is most evident in mature neutrophils and can be contrasted to features of normal forms *(far left, top),* which are usually still present as a subpopulation of the total cells in most cases. Granulocytic dysplasia is characterized by *(left to right, starting at second column)* reduced cytoplasmic granulation, nuclear hypolobation (resulting in the binuclear or single-lobed pseudo–Pelger-Huet forms), hypersegmentation, ringed forms ("rodent cells"), cells with nuclear twinning, and cells with excessive nuclear excrescences. Photomicrographs are from a number of cases of refractory cytopenia with multilineage dysplasia and refractory anemia with excess blasts.

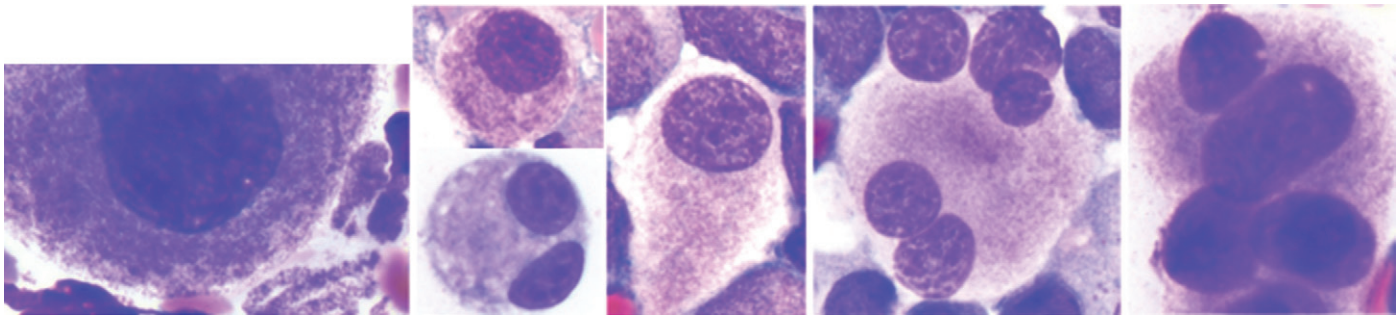

Figure 59-4 MEGAKARYOCYTIC DYSPLASIA. Dysmegakaryopoiesis is most obvious with the presence of micro-megakaryocytes and abnormal larger forms *(panels 2-5)*. These are compared with a normal megakaryocyte at same magnification *(panel 1, far left).* Micro-megakaryocytes have single, two, or four small nuclei, which indicate a low-ploidy level. Normal low-ploidy megakaryocytes can be seen in the bone marrow, but these are immature forms and do not have mature granular cytoplasm with platelet material, as do the micro-megakaryocytes. Larger dysplastic megakaryocytes have multiple, small, widely spaced nuclei. Photomicrographs are from a number of cases of refractory anemia with excess blasts and refractory cytopenia with multilineage dysplasia.

Patients may have disproportionately prolonged bleeding times and abnormalities in platelet aggregation studies.[38,169-171] These may be present even in patients with normal platelet counts. The hallmark is an acquired Glanzmann defect, characterized by abnormal platelet glycoprotein IIb/IIIa. A falling platelet count often is a marker of disease progression. Patients with MDS are at risk for spontaneous bleeding and have increased risk for hemorrhage after surgery and trauma. Again, this is true even in patients without thrombocytopenia.

Autoimmune Manifestations

Immunologic and rheumatologic complications occur frequently in patients with MDS.[172-174] Patients can present with acute episodes of seronegative oligoarthritis or polyarthritis[175,176] as well as symptoms of cutaneous vasculitis, polymyositis, or peripheral neuropathies. Lupus-like symptoms have been reported at the time of the presentation of cytopenias in patients complaining of systemic features of fever, polyarthritis, polychondritis, pleuritis, pericarditis, or even hemolytic

anemia. Presentations involving mucocutaneous ulcerations, iritis, polymyositis, peripheral neuropathy, inflammatory bowel disease, and RBC aplasia have been reported in patients with MDS.[177] In addition, cases of relapsing polychondritis, polymyalgia rheumatica,[172,178,179] Raynaud phenomenon, pyoderma gangrenosum, Sjögren syndrome, and glomerulonephritis have been reported, but their association is less clear.[180] Although these paraneoplastic processes may complicate the initial clinical presentation of MDS, they are often responsive to immunosuppressive agents such as corticosteroids.[181]

Dermatologic Manifestations

Cutaneous complications of MDS are rather uncommon.[182] Neutrophilic dermatosis (Sweet syndrome) is one exception. It is characterized by painful plaque-like lesions that often are associated with fever and arthralgias. These lesions can be present on the face, neck, or upper or lower extremities. Sweet syndrome usually responds to corticosteroid or dapsone therapy. It is often present in patients who are transforming to AML. Other dermatologic presentations include monocytic infiltrates, which are more common in patients with CMML[163,183,184]; chloroma or granulocytic sarcoma, which if present would constitute AML; and petechial lesions, which are common in any patient who presents with severe thrombocytopenia.

Findings on Physical Examination

The physical examination of a patient with MDS typically is rather unrevealing (see Table 59-2). Most patients have pallor because of anemia; petechiae is less commonly present as a result of thrombocytopenia.[185] Signs and symptoms of an infectious process, either bacterial or fungal, should be ruled out. Splenomegaly, hepatomegaly, and lymphadenopathy are rather uncommon except for patients with CMML.[163]

Table 59-3 French-American-British Classification Criteria*

Subtype	Abbreviation	Peripheral Blood	Bone Marrow
Refractory anemia	RA	Blasts <1%	Blasts <5%
Refractory anemia with ringed sideroblasts	RARS	Blasts <1%	Blasts <5%, and >15% ringed sideroblasts
Refractory anemia with excess blasts	RAEB	Blasts <5%	Blasts 5%-20%
Refractory anemia with excess blasts in transformation	RAEB-T	Blasts >5%	Blasts 20%-30% or Auer rods
Chronic myelomonocytic leukemia	CMML	Monocytes >1 × 10^9/L	Any of the above
Acute myelogenous leukemia	AML		Blasts >30%

CLASSIFICATION AND PROGNOSIS OF PATIENTS WITH MDS

Classification Systems

The MDS are a heterogeneous group of clonal hematologic disorders characterized by persistent peripheral blood cytopenias and proliferation of myeloblastic leukemia cells.[21] Since the early 1980s, several groups have developed classification schemes for patients with MDS that can be used for prediction of survival as well as rate of transformation to overt AML. The FAB consensus conference in 1982 described a classification scheme that includes both AML and myelodysplasia.[19] Five categories of MDS were described based on the BM morphology of BM aspirates, specifically requiring patients to have greater than 10% dysplasia within two or more cell lines. Patients were separated into five groups primarily based on the percentage of myeloblasts within the BM aspirate. These categories are RA, RARS, RAEB, RAEB-T, and CMML (Table 59-3). The diagnosis of acute leukemia required at least 30% myeloblasts within the BM or peripheral blood; patients with 30% or fewer myeloblasts were classified as having myelodysplasia.

With the exception of RARS and CMML, the subgroups of MDS are stratified by the percentage of blasts within the peripheral blood or BM. The first two categories, RA and RARS, have fewer than 5% myeloblasts in the BM. Patients with RA and RARS tend to have a longer median overall survival time and a lower rate of progression to acute leukemia than patients in the other categories. Patients with RAEB and RAEB-T have between 5% and 20% or between 21% and 30% myeloblasts within the BM, respectively. These patients often have more severe cytopenias, an increased risk of progression toward acute leukemia, and a shorter overall survival time. Patients with CMML represent a heterogeneous group.[162,163] Some patients have a more MDS-like picture, with significant pancytopenia and trilineage dysplasia within the BM. Other patients have more of a myeloproliferative-like picture, with elevated white blood cell (WBC) count, peripheral monocytosis, splenomegaly, and hypermetabolic symptoms. The median survival time of patients with MDS-CMML was 23 months versus 15 months for patients with myeloproliferative disorder (MPD)-CMML (P = .31), and both groups had nearly identical risk of progression to AML.[186,187]

The FAB classification scheme led to marked improvement in the diagnosis of myelodysplasia. It also served as a general prognostic predictor. However, there still exists considerable variation within the groups with respect to overall survival and clinical features. Several prognostic systems have been devised to better predict the outcome of individual patients. For example, prognosis is inversely related to the number of BM myeloblasts, and cytogenetics have an extremely important impact on overall survival.[188] The International Myelodysplastic Syndrome Risk Analysis Workshop (IMRAW) has developed an International Prognostic Scoring System (IPSS) based on an analysis of more than 800 patients (Table 59-4).[189] This analysis revealed that the most important variables for overall prognosis were specific cytogenetic abnormalities, percentage of myeloblasts within the BM, and number of the lineages involved in the cytopenia. Other adverse prognostic features include age older than 60 years and male sex. Isolated loss of the Y, 5q, or 20q chromosome or the presence of a normal karyotype is associated with a favorable prognosis. Adverse prognostic cytogenetic features included abnormalities of chromosome 7 or complex cytogenetic changes defined as having more than three cytogenetic anomalies. This scoring system divided patients into four categories: low, intermediate-1, intermediate-2, and high-risk groups. The overall median survival for these groups was 5.7, 3.5, 1.2, and 0.4 years, respectively.[189] There are several limitations of using the IPSS for individual patients. First, the IPSS is heavily

Table 59-4 International Prognostic Scoring System for Myelodysplastic Syndrome

Overall Score*	Median Survival (Years)	25% AML Evolution (Years)
Low (0)	5.7	9.4
Intermediate-1 (0.5-1.0)	3.5	3.3
Intermediate-2 (1.5-2.0)	1.2	1.1
High (≥2.5)	0.4	0.2

Data from Greenberg P, Cox C, LeBeau MM, et al: International scoring system for evaluating prognosis in myelodysplastic syndromes (published erratum appears in *Blood* 91:1100, 1998). *Blood* 89:2079, 1997.
AML, Acute myelogenous leukemia.
*The overall score is the sum of the scores from the percent of bone marrow myeloblasts, karyotype, and cytopenias.
The percent of myeloblasts are scored as follows: <5% = 0; 5%-10% = 0.5: 11%-20% = 1.5: 21%-30% = 2.0.
Cytogenetic features associated with good prognosis are scored as 0 and include normal karyotype, loss of Y, 5q–, or 20q–; those associated with a poor prognosis are scored as 1.0 and include abnormalities of chromosome 7 or three or more cytogenetic changes; all other cytogenetic abnormalities are scored as 0.5 and are of intermediate prognosis.
A score of 0 refers to a patient with either zero or one cell lineage cytopenia, and a score of 0.5 is assigned to two or more lineage cytopenias. Lineage cytopenias are defined as hemoglobin <10 g/dL, absolute neutrophil count <1800/mm^3, and platelet count <100,000/mm^3.

Table 59-5 World Health Organization Classifications of MDS

Refractory anemia with unilineage dysplasia
Refractory anemia
Refractory neutropenia
Refractory thrombocytopenia
Refractory anemia with ring sideroblasts
Refractory cytopenia with multilineage dysplasia (with or without ring sideroblasts)
Refractory anemia with excess of blasts-1
Refractory anemia with excess of blasts-2
Myelodysplastic syndrome, unclassifiable
Myelodysplastic syndrome with deletion 5q

The World Health Organization has reclassified chronic myelomonocytic leukemia (CMML) within the myeloproliferative disorders (MPD) and RAEB-T to "AML with multilineage dysplasia." Acute myeloid leukemia (AML) is now classified as ≥20% myeloblasts.
The following are considered AML regardless of blast percentage: t(8;21)-AML1/ETO, t(15;17)-PML/RARA, inv(16) or t(16;16)-CBFβMYH11, and 11q23-MLL.

Table 59-6 World Health Organization Criteria for Diagnosis of Chronic Myelomonocytic Leukemia

Peripheral blood monocytosis >1000/mL.
No evidence of Philadelphia chromosome or *BCR-ABL1* gene
Less than 20% myeloblasts, monoblasts, and promonocytes within the peripheral blood or bone marrow
Dysplastic changes in one or more myeloid lineages. If myelodysplasia is absent or minimal, the diagnosis of CMML can be made if the above three criteria are met and:
Acquired clonal cytogenetic abnormality is present in bone marrow cells *or*
Persistent monocytosis for >3 months and all other causes of monocytosis have been excluded
CMML-1: Blasts <5% in peripheral blood and <10% in bone marrow
CMML-2: Blasts 5%-19% in peripheral blood or 10%-19% in bone marrow

From Vardiman JW, Harris NL, Brunning RD: The World Health Organization (WHO) classification of the myeloid neoplasms, *Blood* 100:2292, 2002.

weighted on the percentage of blasts within the BM aspirate.[190] Second, only a limited number of cytogenetic abnormalities were described within the IPSS, and their prognostic importance is significantly underestimated. Finally, the various cytopenias not only have the same impact on the overall IPSS score but by themselves they are clinically meaningless.

A significant limitation of the FAB classification scheme derives from the arbitrary boundaries imposed within the continuum of disease categories. Patients with RAEB, RAEB-T, and AML likely represent a similar biologic process. Use of 30% myeloblasts within the BM as the division between myelodysplasia and acute leukemia is not biologically consistent and often leads to confusion in the recommendation of treatment options. The European Association of Hematopathologists and the Society for Hematopathology developed a new WHO classification scheme.[20] The WHO defines AML as having a myeloblast count of 20% or greater and drops the RAEB-T category (Table 59-5). Inclusion of CMML in MDS under the older FAB classification scheme was problematic, so within the new WHO classification scheme, CMML has been removed from the MDS category and placed within the myelodysplastic and myeloproliferative disorders (Table 59-6). This change seems more consistent with not only clinical presentation but also with the many treatment choices that are offered to patients with CMML. A new category, refractory cytopenia with multilineage dysplasia (RCMD), also was proposed. This category allows for the classification of patients with morphologic dysplasia within their BM aspirate but who present with isolated neutropenia or thrombocytopenia instead of the typical anemia.

In addition to the number of myeloblasts, the FAB and WHO classification scheme are based on the degree of hematopoietic dysplasia. The FAB classification required patients to have 10% or greater dysplasia in two or more hematopoietic lineages. The WHO modified this requirement, and unilineage erythrodysplasia now is classified as RA or RARS depending on the presence or absence of ringed sideroblasts. Importantly, the dysplasia must have been present for more than 6 months, and no other causes of erythrodysplasia could be present. The WHO introduced a new category of refractory cytopenia with multilineage dysplasia with or without ringed sideroblasts: RCMD and RCMD-S, respectively. Although often subtle, patients with multilineage dysplasia have a significantly poorer overall survival as well as leukemia-free survival compared with patients with unilineage dysplasia.

The WHO classification system has been modified using prognostic scoring variables based on transfusion requirements as well as similar cytogenetic abnormalities within the IPSS.[191] The newer WHO classification-based scoring system (WPSS) is able to stratify patients into five risk groups (Table 59-7). Whereas the very-low-risk group has a survival of 11.3 years and 7% risk of transformation into AML at 10 years, the very-high-risk group has a survival of 0.7 years and 50% risk of transformation into AML at 8 months. Although this scoring system has been validated on a separate cohort of patients, use of the WPSS has not gained widespread popularity. What is clear from the WPSS is that the definition of RBC transfusion "dependency" requires further confirmation and prospective large cohort studies.

Other parameters for evaluating the prognosis of MDS have been assessed in a series of scoring systems that follow different clinical or cytogenetic features, which include WBC count, hemoglobin, platelet count, age, sex, lactate dehydrogenase, and immunophenotyping.[190,192-196] For example, the CD44 antigen, which is a transmembrane glycoprotein, is expressed on BM mononuclear precursor cells as well as peripheral granulocytes and erythrocytes.[193,197] Serum CD44 levels typically are increased in patients with MDS as well as AML and ALL. Increased expression of CD44-6v has been associated with shorter survival time in patients with AML. Flow cytometric analysis has been used to evaluate expression of CD44 on early myeloid cells that coexpress CD66. CD66 typically is expressed on monocytes as well as immature myeloid cells. Low CD44 coexpression on CD66

myeloid cells typically is seen in the early stages of MDS as opposed to increased CD44 expression on CD66-weak myeloid cells, which often is seen in the later stages of myelodysplasia, that is, in patients with increased number of blasts. A shift in CD44 expression therefore often has been associated with a trend toward immaturity or increased number of blasts in patients with MDS; therefore, CD44 expression profiling may be useful as a separate prognostic marker for patients with MDS. However, large prospective studies are warranted.

The angiogenic process is extremely important in the growth and metastasis of many solid tumors.[198,199] Its role in hematopoietic malignancies is less well characterized. Both vascular endothelial growth factor and basic fibroblast growth factor are expressed by myeloblasts. Furthermore, analysis of BM samples from patients with untreated AML showed increased microvessel density.[199,200] Vascular endothelial growth factor has been linked to the promotion of atypical localization of immature myeloid precursors, which is a poor prognostic marker in patients with MDS, especially for signaling out those patients who are at highest risk for disease progression.[119,201,202] Furthermore, microvessel density is markedly higher in patients with RAEB-T compared with the other MDS subtypes, suggesting a role between angiogenesis and transformation to acute leukemia in patients with MDS.

Red Blood Cell Transfusion Dependence

Red blood cell transfusion dependence is associated with a poorer overall survival in patients with MDS. In a retrospective study of 239 patients with low-risk MDS 19% were RBC transfusion dependent and had shorter survival than did patients who had not recently undergone transfusions.[203] A similar retrospective study of 467 patients by Malcovati et al[191] also demonstrated that RBC transfusion dependency in patients with MDS had a negative impact on both overall survival and leukemia-free survival. The negative effect was dependent on the number of transfusions per month and was an independent prognostic variable regardless of cytogenetic risk assessment.

The etiology for the shorter survival in patients with MDS who are RBC transfusion dependent is unclear. Some patients had secondary hemochromatosis as assayed by increased serum ferritin levels, and some patients developed cardiac dysfunction or arrhythmias.[203] Although iron overload is suggested to be a significant component in the increased mortality of transfusion-dependent patients with MDS, prospective studies are needed to accurately assess the effect of iron chelation on survival and subsequent prognosis in patients with MDS who are RBC transfusion dependent.

CYTOGENETIC AND MOLECULAR ABNORMALITIES

Careful examination of the BM aspirate to detect cytogenetic abnormalities is a critical part in establishing the diagnosis of MDS. Although approximately 60% of patients with MDS have a normal karyotype, the presence of characteristic cytogenetic abnormalities may establish the diagnosis in cases in which the dysplastic changes within the BM aspirate are subtle (see Table 59-4).[21] Furthermore, documentation of additional cytogenetic changes may imply an evolving clonal evolution and development of a neoplastic process.

Abnormal karyotypes are identified in about half of all cases of MDS and in more than 80% of therapy-related cases.[6,188] The most common abnormality is trisomy 8. Other common abnormalities include monosomy 5 or 7; loss of the Y chromosome; or deletions involving the long arms of chromosomes 5, 7, 11, 13, and 20. Complex karyotypes, defined as three or more abnormalities, are seen in approximately 15% of cases of MDS and portend an unfavorable prognosis. Chromosomal abnormalities are most often associated with the FAB subtypes RAEB and RAEB-T. The presence of a deletion of the long arm of chromosome 5 (5q–) as the sole abnormality is seen most often in patients with RA[145]; monosomy 7 is rarely seen in this MDS subgroup. Translocations involving platelet-derived growth factor receptor-β (PDGFR-β) have been identified in 5% to 10% of patients with CMML. The first case was identified in a patient with a translocation involving the transcription factor TEL on chromosome 12,[204] but many other fusion partners have now been described. The TEL–PDGFR-β receptor gene product produces a chronic myeloproliferative disorder in mice and is a potential target for tyrosine receptor kinase inhibition with imatinib therapy.

Therapy-related MDS is associated with specific chromosomal abnormalities.[108] Patients who develop MDS or AML after exposure to alkylator therapy often have either a partial loss or complete monosomy of chromosome 5 or 7.[6,7,109] Patients who were exposed to topoisomerase II inhibitors typically present with a monocytic acute leukemia and not MDS. These patients have a high frequency of chromosomal rearrangements involving the MLL gene on 11q23[91] or less commonly the AML1 gene on 21q21. Other chromosomal abnormalities associated with therapy-related MDS include 3p14-21, 6p21, 12p11-17, and 19p13. Mutations involving p53 on chromosome 17p have been described and are associated with a long latency period between toxin exposure and the diagnosis of MDS or AML.[205,206]

Several diagnostic tests have increased the ability to detect cryptic cytogenetic anomalies. Fluorescent in situ hybridization (FISH) uses specific DNA probes to identify each chromosome individually.[207] This method can screen hundreds of cells and does not depend on analysis of dividing cells during metaphase. Thus, the sensitivity can be dramatically increased, but use of FISH is limited to detection of standard cytogenetic abnormalities. Polymerase chain reaction analysis can detect specific gene translocations in either the BM or blood. This assay is rapid and can detect abnormalities present in fewer than 1 in 10,000 cells but also is limited to detection of standard cytogenetic abnormalities.

It is important to realize that a normal karyotype does not exclude the diagnosis of MDS. Normal karyotypes are see in about half of all cases of MDS. This is thought to be attributable to the limitations of standard G banding or the failure of the neoplastic clone to divide in culture. Spectral karyotype analysis or "chromosomal painting" can identify cryptic balanced and unbalanced translocations in most patients with MDS.

Cytogenetic Correlation With Prognosis

One of the limitations with the IPSS is the limited information that was available on cytogenetic data. Cytogenetic analysis since has been performed in more than 2000 patients with MDS and was successful in 97% of these patients.[208] Clonal cytogenetic abnormalities were seen in 52.3% of patients. These included numeric as well as structural chromosomal abnormalities. The limitation in terms of prognosis is the varying degree by which patients receive therapy; therefore, the impact of karyotypic abnormalities on the natural history of myelodysplasia was studied in 1286 patients treated with supportive care only (see Table 59-4). Therefore, how overall and leukemia-free survival are affected by therapeutic intervention is unclear.

In patients with a normal karyotype ($n = 612$), the median survival time was 53 months. This is compared with an 8.7-month survival time for patients with complex abnormalities. The most frequent abnormality involved deletion of chromosome 5q, which occurred in 30% of patients who had a cytogenetic abnormality or 58% of all patients with successful cytogenetic analysis. Isolated deletion of 5q was seen in 14% of patients with clonal abnormalities. Other frequent abnormalities included monosomy 7 or 7q deletion in 21% and trisomy 8 (+8) in 16% of patients with MDS. Less common abnormalities are listed in Table 59-8.

Favorable prognosis measured as a median survival of approximately 3 years was seen in patients with translocations involving chromosome 1q, translocation involving 7q, any chromosome 12 abnormality, translocation involving 17q with a noncomplex karyotype, monosomy 21, trisomy 21, as well as for loss of chromosome X. Median survivals had not been reached for patients with del9q, del12p, and del15q. The favorable survival for these patients was seen only if patients has no additional abnormalities. In addition, 21 other chromosomal aberrations were identified, but their rarity did not allow for prognostic relevance. Therefore, even though numerous cytogenetic abnormalities have been identified, the rarity of a few cytogenetic abnormalities makes prognostic impact limited.

Abnormalities with intermediate prognosis, defined as median survival between 1 and 3 years, was seen in patients with chromosome 3q rearrangements, translocations involving 11q23 as a noncomplex karyotype, and trisomy 19. In addition, regardless of the specific aberrations, an overall correlation was seen between prognosis and extent of abnormalities. Patients with three or more abnormalities had a median survival of 17 months, patients with four to six abnormalities had a median survival of 9 months, and patients with more than six abnormalities had a median survival of only 5 months. This analysis further demonstrates the cytogenetic impact of a complex karyotype on the prognosis of patients with MDS. Cytogenetic analysis remains an important factor in treatment selection as well as monitoring response to therapy. What is unclear from this type of analyses is the impact of pharmacologic therapy on the prognosis of patients with MDS based on their cytogenetic abnormalities.

CLINICAL SYNDROMES

Patients with MDS often present with symptoms of ineffective hematopoiesis.[209] They usually seek medical attention complaining of recurrent infections, bleeding, easy bruising, progressive fatigue and lethargy, or dyspnea on exertion. Occasionally, patients present without symptoms but with abnormal peripheral counts, such as neutropenia, anemia, thrombocytopenia, or a combination of all three. It is important to realize that bleeding can also occur in nonthrombocytopenic patients because of dysfunctional platelets. Patients either die of progressive BM failure or progress to overt AML. A subgroup of patients with less than 5% myeloblasts, RA, or RARS may die of nonhematologic causes, which typifies this affected elderly patient population. In general, patients with MDS have a shorter overall survival time than age-matched control participants, suggesting that BM failure may be additive to other comorbid diseases.[21]

Myelodysplastic syndrome has been reported to coexist with other hematologic malignancies, the most frequent being multiple myeloma, even in previously untreated patients.[210,211] MDS also has been described in patients with hairy cell leukemia, chronic lymphocytic leukemia, non-Hodgkin lymphoma, and large granular lymphocytic leukemia.[212] The association of MDS with these other hematopoietic malignancies suggests a common myeloid or lymphoid stem cell as the transforming cell. However, the association may simply be a statistically random association or be therapy related in some cases. The coexistence of MDS with another hematologic malignancy significantly complicates the treatment options.

5q– Syndrome

Patients with myelodysplasia represent several unique clinical cohorts. Patients with an isolated loss of the short arm of chromosome 5 [del5(q31-q35), or 5q–] are characterized by a prolonged clinical course that progresses to acute leukemia in fewer than 25% of cases.[213,214] Interestingly, anemia seems to be the principal laboratory abnormality. Neutropenia, if present, typically is mild, and platelet counts often remain elevated. The striking pathologic feature is the presence of mononuclear micromegakaryocytes identified in the BM biopsy (Fig. 59-5, *A-C*).

Women account for a larger proportion of cases, up to 70%.[215,216] Patients with 5q– deletions must be distinguished from patients with additional cytogenetic abnormalities because these patients often have a more rapid progression to AML. The large arm of chromosome 5 is rich in genes encoding both cytokines and cytokine receptors.[217] Haploinsufficiency of the ribosomal protein encoding RPS14 gene has been shown to cause the phenotypic features of 5q– syndrome.[218] RNA interference (RNAi) screening technology confirmed the notion that 5q– syndrome is caused by a defect in ribosomal protein RPS14. In addition, a link has been established between acquired 5q– syndrome

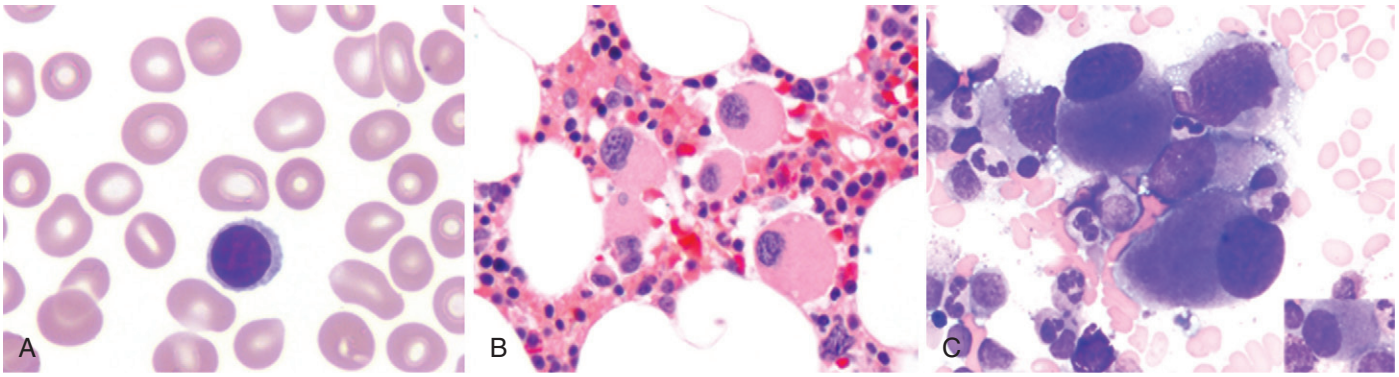

Figure 59-5 SPECIFIC MYELODYSPLASTIC SYNDROMES. The 5q– syndrome (**A** to **C**); hypocellular myelodysplastic syndrome (**D** and **E**), and myelodysplastic syndrome with fibrosis (**F** and **G**). The 5q– syndrome has specific morphologic correlates. There is a macrocytic anemia **(A)** and a cellular bone marrow characterized by increased small monolobated megakaryocytes (**B** and **C**). The megakaryocyte nuclei have little segmentation and are fairly round. Although some true micro-megakaryocytes may be present (**C,** *inset*, same magnification), the typical monolobated forms are not as tiny as the micro-megakaryocytes.

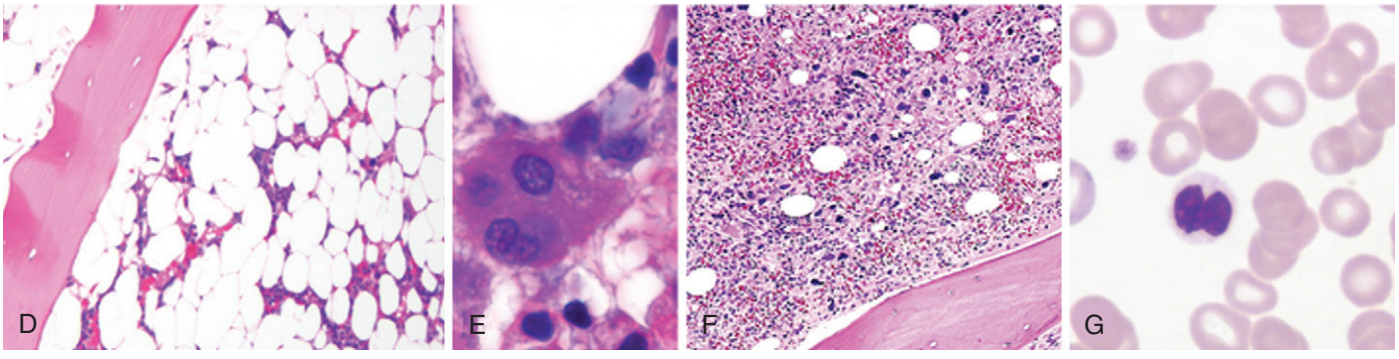

Figure 59-5, cont'd SPECIFIC MYELODYSPLASTIC SYNDROMES. Hypocellular myelodysplastic syndrome (**D** and **E**) can present a diagnostic problem and can be difficult to differentiate from aplastic anemia. Dysplasia may be difficult to evaluate if the smears are paucicellular. The finding of dysplastic megakaryocytes (note small widely separated nuclei, **E**) on the biopsy sample can be helpful. Myelodysplastic syndrome with fibrosis **(F)** can be difficult to differentiate from myeloproliferative neoplasms (MPN). However, the lack of large megakaryocytes, which typically are see in the MPNs along with presence of dysplasia in the circulating neutrophils **(G)** are useful clues to the correct diagnosis.

and congenital BM failure syndromes such as Diamond-Blackfan anemia. Because of the uniqueness of the 5q– syndrome, it often is considered separately from the other myelodysplastic disorders. Patients typically require RBC transfusion as their principal treatment, so careful attention must be paid to management of iron overload. Lenalidomide (Revimid) has been approved for patients with a chromosome 5q abnormality who are transfusion dependent, and its use is discussed in the treatment section.[219,220]

Hypocellular Myelodysplastic Syndromes

The majority of patients with myelodysplasia have hypercellular or normocellular BM. Hypocellular BM is found in a minority of patients (<15%) and is referred to as hypoplastic myelodysplasia (see Fig. 59-5, *D* and *E*).[221] In this subgroup of patients, the morphologic features of the BM may be difficult to differentiate from aplastic anemia, and the definitive diagnosis can sometimes be made from cytogenetic analysis. Cytogenetic abnormalities are rarely found in patients with aplastic anemia. The differential diagnosis of patients with a hypoplastic BM includes not only aplastic anemia but also drug toxicity, PNH, and T-cell large granular lymphocytic leukemia.[222,223] These entities usually can be excluded by flow cytometric analysis of the BM aspirate. The natural history of hypoplastic myelodysplasia is similar to that of the standard variants.

Myelodysplastic Syndrome With Myelofibrosis

Substantial reticulin fibrosis is rarely found in patients with myelodysplasia (see Fig. 59-5, *F* and *G*), although there is an increase incidence in patients with CMML. Myelodysplasia with myelofibrosis can be difficult to distinguish from chronic idiopathic myelofibrosis (agnogenic myeloid metaplasia with myelofibrosis).[121,224] The presence of trilineage dysplasia and the absence of hepatosplenomegaly support the diagnosis of myelodysplasia. However, some cases, may reflect an evolving transformation to a leukemic process, with profound BM fibrosis such as is often seen in acute megakaryocytic leukemia (FAB-M7). Myelofibrosis can occur in all MDS subtypes, and mild fibrosis is seen in more than two-thirds of cases. Marked fibrosis is much rarer and is thought to be present in only approximately 10% of cases.

Patients who develop MDS with myelofibrosis often have rapidly progressive cytopenias, usually without splenomegaly, and often have a poor prognosis.[117,118] Peripheral blood smear usually reveal the heralded "teardrop" cell, and the BM is markedly hypercellular with fibrosis and often dysplastic megakaryocytic proliferation with hypolobated megakaryocytes; many patients have an increased number of myeloblasts. The differential diagnosis is complicated and includes idiopathic or primary myelofibrosis, postpolycythemia vera myelofibrosis with myeloid metaplasia, post–essential thrombocythemic myelofibrosis with myeloid metaplasia, accelerated phase CML, acute leukemia (usually M7 or AML with dysplasia), and acute myelofibrosis.

Myelodysplastic Syndrome—Myeloproliferative Neoplasm Overlap Syndromes

CMML is the quintessential disorder having characteristic findings of both MDS and myeloproliferative neoplasm (MPN) (Fig. 59-6, *A*).[158,162,163] Because the majority of patients with CMML have evidence of trilineage dysplasia, the FAB cooperative group categorized CMML as a subtype of MDS. The FAB criteria for diagnosis included a peripheral monocyte count of 1000/mm^3, less than 5% blasts in the blood, less than 20% blasts in the BM, and absence of Auer rods. The new WHO classification system places CMML with juvenile myelomonocytic leukemia and atypical or BCR-negative CML into the new subgroup MDS–MPD (see Table 59-6).[21]

Many patients with CMML also present with splenomegaly, hepatomegaly, lymphadenopathy, tissue infiltration, or serous effusions.[162,186,187,225] Pleural, pericardial, synovial, and ascitic effusions all have been reported in patients with CMML and are associated with a high circulating monocyte count. Patients with CMML can have vastly different presentations. Certain patients with CMML present with profound cytopenias and marked dysplasia, but other patients have a predominately myeloproliferative form. Because of these two rather distinct clinical presentations, some clinicians separate CMML into two separate entities, with the proliferative form characterized by WBC count greater than 12,000/mm^3, presence of organomegaly, and constitutional symptoms. The nonproliferative form of CMML is characterized by a low WBC count with a relative monocytosis, and complications from cytopenias tend to dominate the clinical picture. The overall prognosis of both forms of CMML is similar, with median overall survival of 19 months, and the absolute number of BM blasts is the dominant prognostic feature.[187]

A subgroup of patients, usually with the proliferative form of CMML, is characterized by the balanced translocation t(5;12)(q33;p13).[204] The consequence of the t(5;12) translocation is fusion of the

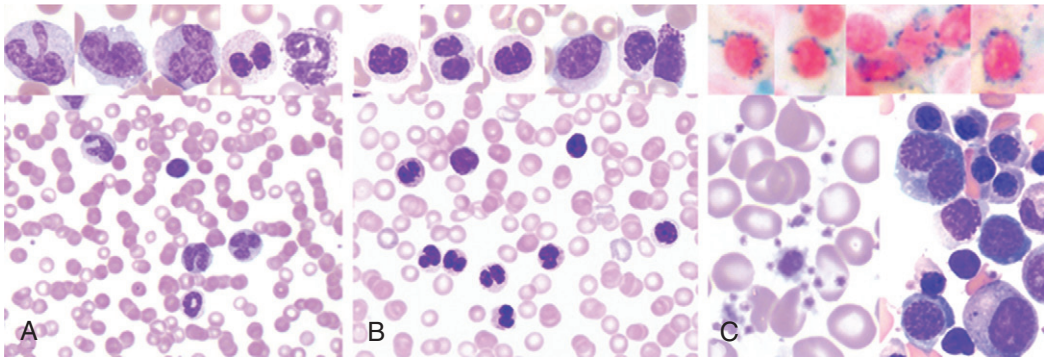

Figure 59-6 OVERLAP SYNDROMES. Chronic myelomonocytic leukemia **(A),** "atypical chronic myelogenous leukemia," *BCR-ABL1*–negative **(B),** and refractory anemia with ringed sideroblasts and thrombocytosis (RARS-T) **(C).** In chromic myelomonocytic leukemia, there can be granulocytic dysplasia and cytopenias (e.g., anemia, thrombocytopenia), but the characteristic feature is the presence of an absolute monocytosis **(A).** "Atypical chronic myelogenous leukemia" (*BCR-ABL1* negative) is essentially a "high-count" myelodysplastic syndrome. There typically is severe granulocytic dysplasia. The absence of an absolute monocytosis excludes chronic myelomonocytic leukemia from the diagnosis. The case shown is characterized by numerous pseudo–Pelger-Huet cells, immature hypogranular granulocytic precursors, and some basophils **(B).** Refractory anemia with ringed sideroblasts and thrombocytosis is characterized by anemia and thrombocytosis in the blood (**C,** *left*), hypercellular marrow with erythroid proliferation (**C,** *right*), and ringed sideroblasts (**C,** *top*).

tyrosine kinase domain of PDGFR-β to a member of the *ETS* family of transcription factors TEL. Fusion of TEL to PDGFR-β constitutively activates the tyrosine kinase domain of PDGFR-β, leading to increased myeloid proliferation. PDGFR-β on chromosome 5q33 also is disrupted by t(5;7), t(5;14), and t(5;10) translocations, resulting in fusion of the tyrosine kinase domain of PDGFR-β to HIP1, CEV14, and H4/D10S170, respectively.[226] The understanding of these findings has led to novel therapeutic approaches using the tyrosine kinase inhibitor imatinib mesylate, with remarkable efficacy and durable responses.[183,227] Unfortunately, PDGFR-β is present in only a minority of cases of CMML.

Therapy-Related Myelodysplastic Syndromes

Therapy-related MDS is becoming more important given the increased dose density currently being administered to patients, for example, those with breast carcinoma.[228-231] Furthermore, the use of myeloid growth factors may inadvertently increase this risk.[232] Therapy-related MDS and AML remain one of the most serious long-term complications of current cancer therapy and often are induced by well-defined chemotherapeutic agents or radiation. The incidence of secondary or therapy-related MDS is increasing.[228] The term *secondary myelodysplasia* refers to the development of disease after either exposure to environmental or therapeutic toxins or from a previously diagnosed hematopoietic disorder. The term *therapy related* should be specifically attributed to the presentation of MDS or AML after the use of intensive chemotherapy or radiation therapy.

Many patients with therapy-related MDS/AML have common chromosomal aberrations or gene mutations. Most importantly, patients with therapy-related MDS behave in a more aggressive fashion regardless of FAB or WHO classification subtype. Patients with therapy-related MDS are not included in the IPSS schema; therefore, specific prognostic factors are limiting. The risk of secondary MDS is highest in patients who already have been exposed to alkylating agent therapy. The cytogenetic abnormalities of alkylating agent therapy–related MDS/AML are quite distinct.[6,10,109] They include either a total loss or a deletion of the long arm of either chromosome 5 or 7. A higher than normal risk for developing therapy-related MDS/AML has been described in long-term survivors of Hodgkin lymphoma, non-Hodgkin lymphoma, multiple myeloma, and gastrointestinal cancers, specifically those treated with semustine (methyl-CCNU).[233-236] The estimated actuarial risk in patients treated for Hodgkin lymphoma is between 6% and 9%. A 17% actuarial risk has been reported in patients treated for multiple myeloma.

The risk of developing MDS after adjuvant treatment of breast cancer, small cell lung cancer, testicular cancer, or ovarian cancer is low but increases with use of regional radiation therapy. Topoisomerase II inhibitors also can induce therapy-related AML[91] but typically involves a balanced translocation of chromosome band 11q23 and less commonly involves 3q26 and 21q22. The topoisomerase II inhibitors include the epipodophyllotoxins and anthracyclines. As opposed to prior exposure from alkylating agents, MDS seldom precedes therapy-related AML caused by the topoisomerase II inhibitors.

Use of adjuvant therapy for treatment of early-stage invasive breast carcinoma has been associated with therapy-related MDS/AML. The incidence of therapy-related MDS/AML after treatment of early-stage breast cancer with mastectomy alone is only 0.27%.[229,237,238] A case-control study of 82,700 women treated for early-stage breast cancer during the 1970s and 1980s reported that the typical cyclophosphamide, methotrexate, and fluorouracil (CMF) regimens with a low cumulative dose of cyclophosphamide is associated with an additional five cases of leukemia for every 10,000 women treated over 10 years.[239] However, with the current use of anthracycline-based adjuvant chemotherapy regimens (cyclophosphamide, epirubicin, fluorouracil [CEF]; or fluorouracil, Adriamycin [doxorubicin], cyclophosphamide [FAC]), the risk of therapy-related MDS/AML has increased compared with the classic CMF regimen. Rates of therapy-related MDS/AML now approach 1.5% after 5 to 10 years of follow-up. There is an even greater risk in women who received radiotherapy.[240,241] In patients who receive four cycles of standard anthracycline and cyclophosphamide therapy (cyclophosphamide 600 mg/m^2 and doxorubicin 60 mg/m^2 per cycle), the risk appears quite low. In one study, the incidence of therapy-related MDS/AML in patients who receive four full cycles of cyclophosphamide and anthracycline chemotherapy was only 0.1% with the median follow-up of 5 years. However, women seem to have a higher risk for therapy-related MDS/AML in the National Surgical Adjuvant Breast and Bowel Project (NSABP) protocols B-22 and B-25 in which a higher dose of cyclophosphamide as well as doxorubicin were used.[237] Of potential importance was the use of G-CSF in these regimens. In one retrospective study of patients with breast cancer, use of G-CSF was associated with doubling of the risk of therapy-related MDS/AML.[232]

A history of autologous BM transplantation (BMT) has been associated with a substantial risk of developing therapy-related MDS and AML.[240,242-249] The cumulative probability of developing therapy-related MDS/AML after autologous SCT ranges from 4% to 14%, depending on the series. A retrospective study by Friedberg et al[250] reported a 19.8% actuarial risk of developing MDS by 10 years. All of the 552 patients analyzed in this study were treated with cyclophosphamide and total body irradiation. The patients who developed MDS had on average a lower number of cells reinfused per kilogram at autologous BMT. The increased incidence of therapy-related MDS/AML has been associated with use of radiation therapy as part of the conditioning regimen, but other risk factors include advanced stage, number and type of prior courses of chemotherapy, and exposure to radiation therapy before transplantation. The prognosis of patients with therapy-related MDS or AML remains extremely poor.

Therapy-related MDS and AML are characterized by three distinct groups of cytogenetic abnormalities.[89,108] The first is an unbalanced aberration along chromosome 5 or 7. Patients typically have loss of the whole chromosome 5 or 7 or loss of various parts, specifically the long arm of chromosome 5 or 7. Another frequently observed abnormality is the gain of a whole chromosome 8 (trisomy 8).[39] Abnormalities of chromosomes 5, 7, and 8 are seen in 15% to 25% of cases in de novo MDS but comprise approximately 50% to 70% of cases with therapy-related MDS. Similarly, they occur in 15% to 25% of cases of de novo AML but in 40% to 50% of therapy-related AML. A second cytogenetic subgroup comprises recurrent balance translocations involving the MLL gene on chromosome 11q23.[251,252] Patients with this abnormality typically present with AML without a myelodysplastic prodrome. From 15% to 20% of patients with therapy-related AML have rearrangements of the MLL gene; this abnormality typically is not seen in patients with therapy-related MDS. In fact, the WHO has redefined patients with MLL gene rearrangements or patients with t(8;21) or t(16;16) or inv(16) as having AML regardless of the absolute blast count.[20,158] The final group of patients with therapy-related MDS consists of patients with a normal karyotype or other chromosomal aberrations. This group comprises 50% to 60% of de novo MDS but only 5% to 10% of therapy-related MDS and 10% to 15% of therapy-related AML.

With respect to specific molecular abnormalities, the most common specific gene mutation involves the MLL gene on 11q23, but other abnormalities have been identified, namely, AML1 on 21q22, the RARA locus on chromosome 17q21, and CBFB on chromosome 16q22.[93,94,97,105,107,252-254] Rearrangements of these genes lead to a dominant loss of function of the transcription factor, which results in impairment of differentiation. It is thought that by interfering with myeloid differentiation, leukemia will result. In addition, other abnormalities have been identified, including mutations of the nucleophosmin gene NPM1, which has been designated a class II mutation in leukemogenesis.[255] The critical genetic consequences of unbalanced chromosome aberrations in MDS and AML are unclear. Deletions of chromosome 17p13 or loss of whole chromosome 17 were thought to involve the p53 gene.[206,256-259] In addition, data have suggested that monosomy 5 or loss of the long arm of chromosome 5 is related to haploinsufficiency of the *EGR1* gene.[260] However, a study from the Look laboratory at the Dana Farber Cancer Institute has implicated haploinsufficiency and promoter methylation of

CTNNA1, the gene encoding α-catenin.[76] How either of these genetic defects relates to the haploinsufficiency of the ribosomal protein encoding RPS14 remains unclear.[218]

Refractory Anemia With Ringed Sideroblasts with Thrombocytosis

Some patients with MDS present with marked thrombocytosis. Most patients have RARS but with a markedly elevated platelet count and therefore have been reclassified as having RARS-T (see Fig. 59-6, *C*).[167,261-264] BM aspirate and biopsy show features consistent with a myeloproliferative and myelodysplastic overlap syndrome. Importantly, the megakaryocytes resemble those seen in essential thrombocythemia. Patients with RARS-T often have evolved from a low-grade MDS category, such as RA or RARS, but have acquired a Janus kinase 2 (JAK2) V617F mutation. This mutation is relatively uncommon in other patients with MDS; therefore, RARS-T represents another JAK2 mutation-associated chronic myeloproliferative disorder.[265-267]

According to the WHO, patients with RARS-T are classified under the provisional MDS/MPD category and listed as unclassifiable.[268] Given the rarity of this syndrome, definitive estimates of overall survival and time to leukemic transformation are unclear. However, a retrospective analysis of 23 patients with RARS-T revealed a 5-year survival of 86% compared with 62% in patients with RARS who did not have a JAK2 V617F mutation.

3q21-q26 Syndrome

Patients with MDS who contain a 3q21-q26 cytogenetic abnormality often have profound trilineage dysplasia, especially of the megakaryocytes.[269] Patients can present with either MDS or AML and typically have a normal or increased platelet count. Cytogenetic analysis at the time of diagnosis often reveals at t(1;3), inv(3), or t(3;3) abnormality. Patients with these cytogenetic abnormalities have an extremely poor response to chemotherapy and, as a result, a poor overall prognosis. The peripheral blood smear often reveals giant platelets or even circulating megakaryocytic fragments. In addition, hypogranular megakaryocytic forms and micromegakaryocytes may be present in the BM aspirate. These morphologic abnormalities involving the megakaryocytes are accompanied clinically with an increased risk of bleeding despite either a normal or increased absolute platelet count. Platelet aggregation studies show decreased platelet aggregation to collagen and epinephrine and may explain the increased risk of bleeding seen in these patients.[38,171]

TREATMENT

General Principles

Treatment of patients with MDS remains challenging for several reasons. First, patients with this disorder are likely to be elderly, so comorbid disease and performance status are critical components in deciding on specific therapy. Second, the disease is heterogeneous, making therapies for one type of MDS less optimal than those for others. Given the lack of precise pathophysiologic understanding of more than a few MDS subtypes, designing truly targeted therapies is impossible. We are left with agents that deal with abnormalities generally thought to play a role in MDS, such as underactive or overactive apoptosis, failure to express silenced genes required for hematopoietic cell differentiation, or overabundant angiogenic signaling. Finally, there is no widely accepted standard of care in that very few, if any, modalities have been definitively proven to change the natural history of this disease. Until recently,[270] response criteria for MDS were not standard, making for difficult interpretation of the multiple phase II trials that included trial-specific response criteria.

The primary goal of most therapeutic strategies in neoplastic diseases is improvement in overall survival. Although this remains the desired result for treatment of patients with MDS, less formidable achievements also might be useful. Such benefits might include a delay in time to transformation to leukemia, response rate (rigorously defined), decrease in transfusions, decreased infection, hematologic improvement, and improved quality of life. The only modality historically associated with an appreciable degree of long-term disease-free survival is allogeneic BMT.[270,271] This modality is resource intense, potentially highly toxic, and heretofore available only to a minority of patients with MDS because of age and performance status requirements. On the other hand, analysis of the role of the myriad other valuable medical therapies is complicated (see boxes on Management Guidelines for a Newly Diagnosed Patient With

Management Guidelines for a Newly Diagnosed Patient With Myelodysplasia

The only known curative modality for patients with MDS is SCT. Therefore, all appropriate candidates should be considered for SCT. They include patients younger than 70 years (age 75 years at some centers), with a reasonable performance status and no significant comorbidity. Retrospective data from the International Bone Marrow Transplant Registry suggest that patients with low-risk disease (IPSS low or intermediate-1) should undergo SCT only at the time of disease progression (see text and Table 59-10). Disease progression includes progressive, clinically significant cytopenias such as progressive RBC or platelet transfusion dependency or transformation to a high-risk disease. Transformation to high-risk MDS typically is manifested by an increase in the number of bone marrow blasts but also could represent accumulation of additional cytogenetic abnormalities.

Patients with low-risk disease should be carefully analyzed for the presence of a deletion of the long arm of chromosome 5. Patients with a deletion of 5q or those who have the 5q syndrome should start taking lenalidomide at the time they become RBC transfusion dependent. For patients with hypoplastic MDS who are younger than 6 years of age, have a low transfusion requirement, and have no increase in marrow myeloblasts, immunosuppressive therapy should be considered with ATG and a calcineurin inhibitor. In all other patients with low-risk MDS, the addition of an ESA should be considered, but only in patients with a serum EPO level less than 500 mU/mL. For patients who do not respond to initial ESAs, addition of a myeloid growth factor (GC-SF or GM-CSF) should be considered. In patients who do not respond or those with an elevated EPO level, aggressive supportive care should continue. The addition of a hypomethylating agent, such as azacytidine or decitabine, may improve the hematologic parameters, but the overall experience of hypomethylating agents in patients with low-risk MDS is limited. The addition of lenalidomide is another option for patients who have isolated anemia, but lenalidomide has no impact on the myeloid or megakaryocytic lineages in patients without the 5q abnormality. Although controversial, iron chelation therapy can be considered for patients with low-risk MDS and a serum ferritin level greater than 1000 mcq/L.

All patients with high-risk MDS classified by an IPSS score of intermediate-2 or higher or patients with more than 10% bone marrow blasts should be seen at a transplant center for consideration of SCT if they are appropriate candidates. For patients who are not eligible for transplantation, a hypomethylating agent should be initiated at the time of presentation. Hypomethylating agents such as azacytidine and decitabine are associated with a small but reproducible complete remission rate, and evidence from Europe has demonstrated that azacytidine may improve the median overall survival. In addition, regardless of the IPSS risk category, all patients should be considered for clinical trial participation. Hopefully, novel strategies will make an impact not only on patient quality of life but also improve the median survival of patients with MDS.

Role of Iron Chelation in the Management of Patients With Myelodysplasia

The development of secondary hemochromatosis is associated with significant morbidity in chronic hemoglobinopathies such as thalassemia major, Blackfan-Diamond syndrome, and sickle cell anemia. Iron chelation therapy has been shown to improve the outcome in patients with these disorders. However, the same cannot be said for patients with MDS. The majority of patients with MDS become RBC transfusion dependent because they are exposed to a significant amount of intravenous iron. Each unit of packed RBCs has approximately 200 to 250 mg of elemental iron. More than 75% of patients with MDS who receive chronic RBC transfusions will develop evidence of secondary hemochromatosis documented by a serum ferritin level of 1000 mg/mL or higher. This typically occurs after patients have received a total lifetime of 40 units of packed RBCs. Nevertheless, it remains difficult to document true organ failure as a result of iron overload in most patients with MDS. In patients with MDS, a serum ferritin level of 1000 mg/mL or higher is associated with a reduced median overall survival. What has not been demonstrated in a prospective fashion is whether the addition of iron chelation therapy can improve survival.

Patients with high-risk MDS have a shortened overall survival time as a result of progressive cytopenias resulting in infection, bleeding diatheses, or transformation to AML. In these patients, the role of iron chelation therapy is unlikely to improve the median survival. However, in patients with low-risk MDS, the natural history of the disease is markedly different. Many patients have an indolent course, with a median overall survival longer than 3 years. In addition, use of disease-modifying agents, such as lenalidomide, in patients with 5q syndrome may alter the natural history of the disease.

Two studies have demonstrated that iron chelation therapy is associated with an improved median survival in patients with low-risk MDS. Both studies have limitations. In the Canadian study, which was a retrospective analysis of 178 patients, only 18 patients received iron chelation therapy. The other study from the French MDS group was a nonrandomized prospective analysis of 165 patients of whom 46% received iron chelation therapy. In this latter study, various regimens of iron chelation were used, but no formal assessment of individual iron stores was made. Thus, the role of iron chelation therapy for patients with MDS is unclear. If it has a role, it should be reserved for patients with low-risk MDS because they are expected to have a prolonged median survival time, especially patients who are benefiting from their therapy.

Myelodysplastic Syndromes in Young Patients

Although MDS typically occurs in patients older than 60 years (median age, 70 years), younger individuals also can be affected. Data on the treatment of young patients with MDS who have an indolent or low-risk presentation are unclear. When the IPSS was developed, few patients were younger than 60 years, but it was clear that young patients within the low and intermediate-1 risk groups had significantly better survival than did older patients within the same IPSS risk group. Because the outcome from SCT is related to patient age, the best approach for young patients with MDS who have a low to intermediate-1 IPSS score remains debated.

Cutler et al[389] demonstrated a superior outcome when patients in low or intermediate-1 IPSS risk groups were transplanted at the time of disease progression as opposed to the time of their initial diagnosis. Furthermore, data from the German registry revealed that 86% of patients younger than 50 years with low-risk disease were alive at 20 years, and patients with an intermediate-1 IPSS score had a median survival of 176 months. Therefore, patients with low or intermediate-1 risk MDS who are younger than 50 years should be observed, and SCT should be delayed until disease progression. Disease progression includes the development of significant transfusion requirements, progressive cytopenias, or transformation to a higher IPSS subgroup.

Myelodysplasia, Role of Iron Chelation in the Management of Patients With Myelodysplasia, Myelodysplastic Syndromes in Young Patients, and Erythropoietin-Stimulating Agents in Patients With Myelodysplastic Syndromes).

Supportive Care

If there is standard therapy for patients with MDS (other than relatively rare young patients who may be BMT candidates), it is supportive care. Supportive care generally consists of administration of blood products and antibiotics when needed. Most also would consider use of iron chelation therapy and hematopoietic growth factors as reasonable supportive care adjuncts.

The development of hematopoietic growth factor therapy held both promise and peril as a therapeutic strategy in the treatment of patients with MDS. Certainly, if the platelet count, hematocrit, and neutrophil count are low, use of an agent that could stimulate growth of the appropriate precursor cell might prove beneficial in ameliorating symptoms and complications associated with the given cytopenia. On the other hand, it was recognized early on that in most cases, the pathophysiology of MDS had nothing to do with the failure of growth factor availability. For example, levels of EPO, the renally elaborated protein that regulates RBC production,[272] usually are elevated in anemic patients with MDS[273]; however, the intrinsically diseased BM cannot respond. Moreover, it has been recognized for some time that leukemic cells, the neoplastic counterparts of normal BM stem cells, harbor growth factor receptors and can be induced to proliferate in vitro in response to these agents.[274] As such, it was feared that particularly the myeloid growth factors might be leukemogenic in patients with MDS. Although clinical studies have failed to confirm a major deleterious leukemogenic effect, they also have shown that these treatments do not prevent infection or prolong life expectancy. Nonetheless, when used selectively, hematopoietic growth factors may be useful in the management of certain patients with MDS.

Management of Red Blood Cell Transfusion Dependence

Because most patients with MDS are anemic, which is a major factor in fatigue and poor quality of life, the issue of primary management of this finding is critical. Transfusion of packed RBCs, generally when the patient is symptomatic or when the hemoglobin falls below 8 to 9 mg/dL, is the usual approach. RBCs should be irradiated to prevent transfusion-associated graft-versus-host disease (GVHD).[275] Whether routine depletion of WBCs to reduce alloimmunization is required is controversial.[276] Despite the caveat about high EPO levels in MDS patients, patients can respond meaningfully to this agent, perhaps because a blunted response curve[277] allows pharmacologic doses of recombinant EPO to stimulate erythropoiesis in MDS. The potential for exogenous EPO to raise the hematocrit, decrease transfusion requirements, and possibly improve the quality of life in patients with MDS spurred the generation of many phase II and III trials with various doses and schedules of EPO. Although the initial trials generally used three times per week dosing (based on the successful use of this drug in patients with renal failure),[278] the impracticability of this approach (based on third-party payment rules requiring patients receive drug administration in a doctor's office) have generated weekly dosing schedules. Moreover, the availability of long-acting EPO[279] has furthered the use of more intermittent schedules.

Erythropoietin-Stimulating Agents in Patients With Myelodysplastic Syndrome

The safety of ESAs, recombinant human erythropoietin (rh-EPO; Epogen or Procrit) and darbepoetin (Aranesp) has come into question, specifically in patients with chemotherapy-induced anemia and chronic renal failure. ESAs can increase hemoglobin and ameliorate the symptoms from anemia that develop in patients with cancer who are undergoing chemotherapy and those with chronic renal failure. However, treatment also increases the risk of thromboembolic complications. Increased risk of tumor recurrences also has been noted.

For patients with chronic renal failure, two trials have demonstrated that patients assigned to a high targeted hemoglobin experience significantly more adverse events, including death, chronic heart failure, myocardial infarction, and stroke than do patients assigned to lower targeted hemoglobin. Use of ESAs for treatment of anemia in patients with MDS has remained a standard approach used by most physicians. Interestingly, most physicians are unaware that this remains an off-label use because regulatory authorities have not approved ESAs for use in patients with MDS. The efficacy of ESAs in MDS has been difficult to tabulate given the changing definition of response. Now with most authors using the IWG criteria for response, we have a better appreciation for the low but reproducible responses seen with use of ESAs in patients with MDS. The hemoglobin response from an ESA in patients with MDS ranges from 20% to 40%. It is important to note that a major hemoglobin response includes the development of transfusion independence as well as an increase in hemoglobin of at least 2 g/dL from baseline measurements.

There have been many concerns regarding the safety of ESAs in patients with MDS. Importantly, no significant adverse events, including thromboembolic complications, have been noted in multiple studies. Mounting evidence indicates that a lower baseline serum EPO level is associated with a higher response rate; therefore, all patients should have a baseline EPO level measured before initiation of an ESA (see text and Table 59-9). Patients with serum EPO levels greater than 500 mU/mL have such a low response rate to ESAs that alternative strategies should be considered first. ESA treatment requires a long duration to see maximum benefit, and because of increased iron utilization, concurrent iron administration may be required to achieve a maximum response. In addition, use of ESAs did not appear to be associated with higher rates of progression to AML. More importantly, it appears that amelioration of chronic anemia in patients with MDS not only may improve their quality of life but also may change the natural history of the disease (see text).

Table 59-9 Algorithm for Predicting Response to Erythropoietin and Granulocyte Colony-Stimulating Factor in Lower Risk Myelodysplastic Syndrome*

Parameter	Value of Parameter	Score
Serum erythropoietin	<100 mU/mL	+2
	100-500 mU/mL	+1
	>500 mU/mL	–3
RBC transfusions	<2 units/mo	+2
	≥2 units/mo	–2
Score	Response	
Score >+1	Good response = 74%	
Score –1 to +1	Intermediate response = 23%	
Score <–1	Poor response = 7%	

Adapted from Hellstrom-Lindberg E, Ahlgren T, Bequin Y, et al: Treatment of anemia in myelodysplastic syndromes with granulocyte colony-stimulating factor plus erythropoietin: Results from a randomized phase II study and long-term follow-up of 71 patients. *Blood* 92:68, 1998.
*Response definitions:
Complete = Stable hemoglobin >11.5 g/dL.
Partial = Increase in hemoglobin with >1.5 g/dL or cessation of red blood cell (RBC) transfusion.

Selected phase II trials[280-283] using recombinant human erythropoietin (rh-EPO) in patients with MDS report response rates in the 25% range. However, definitions of response are highly variable, most trials were conducted before common use of the International Working Group (IWG) criteria,[270] and the clinical benefit of such responses can be quite heterogeneous. For example, an increase in hemoglobin of 1 to 2 mg/dL could have biologic but very little clinical significance unless the patient becomes transfusion independent. Older patients with MDS who have clinical or subclinical impairment of renal function leading to a relatively lower level of serum EPO for a given degree of anemia might be good candidates for a therapeutic trial with this agent.

Although most patients with MDS have abundant supplies of iron because of prior transfusion or high gut absorption, a small subset of patients may be iron deficient. Therefore, it is important to review iron stores at the time of diagnostic BM examination and, if absent, to provide supplemental iron because EPO responsiveness requires an iron-replete state. Because response to EPO in MDS may be delayed, the drug should be continued for at least 8 weeks before therapeutic failure is declared. Although the drug is well tolerated, keeping severely anemic or heavily transfusion-dependent patients on EPO for long periods makes little sense and is costly. Several studies have suggested that adding the myeloid growth factor G-CSF at low doses to EPO can enhance the erythropoietic response.[284-286] Using the combination of EPO plus G-CSF initially or adding G-CSF after the effect of EPO is stable or waning may lead to response rates in the 40% range, which appear to be higher than with EPO alone. Nonetheless, the lack of a true prospective randomized trial of EPO with or without G-CSF has limited the wide acceptance of this strategy.

For patients with low-risk MDS, rh-EPO remains the most commonly used initial therapeutic approach for treatment of patients with MDS who are transfusion dependent to RBCs. In patients with MDS, only 15% to 30% will experience an erythroid response to rh-EPO. There are good predictive features for an observed response. Predictors for response to EPO are unclear. A decision model was developed by Hellstrom-Lindberg[286] (Table 59-9). Patients with MDS who had an EPO level less than 500 mU/mL, low RBC transfusion requirements, and BM blasts less than 10% had a favorable chance of responding to rh-EPO. Interestingly, the presence of a deletion 5q with or without additional cytogenetic abnormalities did not affect the response rate but did shorten the response duration.[287] In addition, patients who do not have RARS[288,289] have a higher and more durable response. The Nordic MDS group suggested that patients with multilineage dysplasia have a poorer response to rh-EPO compared with patients with unilineage erythroid dysplasia (75% vs. 9%; $P = .003$).[290] However, this has not been uniformly observed. The addition of a granulocyte colony-stimulating factor (G-CSF or GM-CSF) to single-agent rh-EPO can increase response rates by 20% to 40%.[60,284,286,291-293] Darbepoetin, a hypersialated erythropoietin-stimulating agent (ESA), has a longer half-life than rh-EPO and has yielded similar response rates when administered at intervals of every 1 to 3 weeks.[293] Response durations to either ESA agent range from 1 to 2 years, with longer responses associated with lower blast percentage as well as a low to intermediate IPSS score.

Few data regarding the safety of ESA use in patients with MDS are available. Use of ESAs for treatment of chemotherapy-induced anemia and chronic renal insufficiency has been associated with increased morbidity and mortality in many but not all randomized trials. In patients with chronic renal insufficiency, a hemoglobin level of 10 to 12 g/dL was often targeted in a randomized trial in which patients assigned to a targeted hemoglobin of 13.5 g/dL experienced

significantly more adverse events, including death, chronic heart failure, myocardial infarction, and stroke compared with patients assigned to a lower targeted hemoglobin.[294] These findings have been supported by a more recent meta-analysis of nine randomized studies comparing different hemoglobin targets, suggesting that patients with higher hemoglobin concentration display significantly higher rates of all-cause mortality, including complications from arteriovenous access thrombosis as well as from poorly controlled hypertension.[295]

As for patients with MDS, amelioration of anemia is thought to improve quality of life, specifically in responding patients. In addition, decreasing the need for transfusion support may have a dramatic impact on RBC supplies as well as decrease the risk of secondary hemochromatosis. More important is the observation that transfusion dependency has a negative impact on the natural history of patients with MDS.[191] A retrospective case-matched study of patients with MDS treated with supportive care compared with rh-EPO demonstrated that patients with a low RBC transfusion requirement (<2 units of RBCs per month) had a significant survival advantage with the addition of rh-EPO (hazard ratio, 0.56; $P = .015$).[296] Of major importance is the fact that administration of rh-EPO had no significant adverse effect on leukemic evolution. In fact, there was a suggestion that responding patients had a lower risk of AML progression compared with patients who did not respond. These findings were corroborated by another study of 419 patients with MDS who were treated with an ESA.[287] Patients were compared with case-matched control participants with MDS managed by supportive care without use of rh-EPO. Similarly, a survival advantage was observed in the responding patients. Finally, a phase III prospective cooperative group trial also demonstrated a survival advantage in patients with MDS treated with rh-EPO with or without use of the myeloid growth factor G-CSF.[291] This was compared with best supportive care. The median survival time in patients responding to treatment was 53 months compared with 23 months in nonresponding patients. These data importantly suggest that decreasing RBC transfusion requirements and resolution of severe anemia in patients with MDS may improve not only overall survival in low-risk patients but also decrease the risk for AML progression.

Management of Neutropenia

Because of the quantitative and qualitative defects in neutrophils, infections are common in patients with MDS and are a source of considerable morbidity and occasional mortality.[21] No data support the routine use of prophylactic granulocyte transfusions or antibiotics in MDS. When fears about the ability of the myeloid growth factors G-CSF and GM-CSF to stimulate clinically meaningful blast cell proliferation were diminished, studies conducted in the late 1980s and early 1990s documented the efficacy of these agents in routinely increasing the number of normal WBCs.[297-300] However, the few randomized studies performed did not demonstrate a decrease in the infection rate or an improvement in life expectancy despite achieving blood count improvement.[301] Such a discrepancy may reflect the maturation of dysfunctional or hypofunctional neutrophils that, although increased in number, cannot provide significant host defense benefit. Moreover, the mortality rate from infectious causes in MDS before conversion to AML probably is low. Although selected patients with recurrent suppurative infections might be candidates for myeloid growth factors, these agents should not be routinely used in MDS.

Management of Thrombocytopenia

Patients with MDS, particularly with more advanced subtypes, may have severe chronic thrombocytopenia with associated mucosal bleeding. Thrombocytopenia, defined as platelet count less than 100 × 109/L, occurs in 40% to 65% of patients with MDS. This problem may become life threatening if a significant bleed occurs in the brain or gastrointestinal tract. The reported incidence of hemorrhagic complications ranged from 3% to 53%, and the frequency of death as a result of hemorrhage was 14% to 24% of such cases.[165] Nonetheless, platelet transfusions should be used judiciously in MDS because overuse may result in alloimmunization and failure to respond to subsequent transfusions even if leuko-poor products are used.[276] As in the case of RBC transfusions, platelets should be irradiated before use.[275] Therefore, rather than giving transfusions below a certain threshold, as is routinely done after chemotherapeutic administration,[302] it makes more sense to use clinical bleeding as the trigger. Use of the antifibrinolytic agent ε-aminocaproic acid can be considered for the thrombocytopenic patient who is bleeding but is not responding to transfusional therapy.[303]

Levels of thrombopoietin, the homeostatic hormone responsible for maintaining normal platelet counts, are elevated in thrombocytopenic patients with MDS,[304] making response to pharmacologic doses of the recombinant protein unlikely. However, neither native thrombopoietin nor its pegylated derivative megakaryocyte growth and development factor (MGDF) has been tested in patients with MDS. MGDF underwent limited testing as a supportive agent in patients with AML after induction chemotherapy.[305,306] Not only was MGDF not associated with a decrease in bleeding or need for platelet transfusions in AML, but its development was discontinued because of development of antiplatelet antibodies and thrombocytopenia in normal volunteers. IL-11, a cytokine with pleiotropic effects, is approved for use as a supportive agent for prophylaxis against severe thrombocytopenia after myelointense chemotherapy for solid tumor patients.[307] Limited testing of this agent alone in MDS patients[308] or after myelosuppressive therapy with the antibody–toxin conjugate gemtuzumab ozogamicin demonstrated side effects (e.g., fluid retention) and limited efficacy.

AMG531 (romiplostim) is a thrombopoiesis-stimulating Fc-peptide fusion protein (peptibody) that is being investigated in patients with idiopathic thrombocytopenic purpura.[309] AMG531 binds and activates the thrombopoietin receptor myeloproliferative leukemia virus oncogene (c-Mpl). Phase II studies have demonstrated durable platelet responses in patients with idiopathic thrombocytopenic purpura and the ability of these patients to subsequently discontinue corticosteroid therapy. AMG531 also is being developed in patients with chemotherapy-induced thrombocytopenia as well as in patients with MDS. A phase I/II study of AMG531 in patients with low-risk MDS who also were thrombocytopenic has been completed. Durable platelet responses were seen in 54% of patients with a decreased need for transfusions and a lower number of severe hemorrhagic events in responding patients.[310] Future studies will further explore the response rates of AMG531 in patients with MDS-related thrombocytopenia as well as patients currently undergoing hypomethylating therapy who develop thrombocytopenia as a complication of therapy.

Eltrombopag (SB-497115) is an oral nonpeptide thrombopoietin receptor agonist that binds to the transmembrane domain of the Mpl receptor, thereby inducing proliferation and differentiation of megakaryocytes.[311] Eltrombopag increased platelet production in patients with thrombocytopenia secondary to hepatitis C virus infection and in adult patients with relapsed or refractory chronic idiopathic thrombocytopenic purpura. Its use in patients with MDS has not been reported.

Management of Iron Overload

In patients with MDS, particularly those with indolent histologic subtypes or good prognoses based on the IPSS schema, administration of well over 100 units of packed RBCs is not unusual. The high iron load associated with such transfusion requirements may be harmful to the liver, pancreas, heart, and central nervous system.[312] Chelation therapy with either deferoxamine by continuous subcutaneous administration or the oral agent deferasirox (ICL670) can be administered to such patients, usually after they have received at least 25 to 30 units of blood.[313,314] Side effects of deferoxamine include cataract formation and chronic skin irritation from the subcutaneous injections. Chronic administration of deferoxamine is cumbersome,[315] is not well tolerated, and chelates only approximately 25 mg/day of

iron, which compares unfavorably with the 250 mg given in a single unit of blood. Although beneficial in children with thalassemia who receive frequent transfusions,[316] the role of desferoxamine is limited in patients with MDS.

Deferasirox initially is administered at a dose of 20 mg/kg once per day and escalated to 30 or 40 mg/kg/day depending on the response. Typical side effects include development of gastrointestinal toxicity principally manifested as abdominal pain, nausea, vomiting, and diarrhea. Unfortunately, these side effects make dose escalation difficult in some patients. Deferasirox typically is used in patients with low-risk MDS and has been associated with decreases in serum ferritin levels. Prospective randomized trials using this agent in patients with low-risk MDS are warranted before its use can be universally recommended.

The development of secondary iron overload is difficult to define.[209] Secondary iron overload often is defined in patients with serum ferritin level greater than 1000 mg/mL. Patients who have an elevated serum ferritin level greater than 1000 mg/mL have decreased overall survival.[191,317] Whether poorer clinical outcomes are related to increased number of transfusions, a consequence of iron overload, or are caused by progressive BM dysfunction and failure that results in lower hemoglobin levels is unclear. Although these data are provocative, further evaluation and independent validation are needed, especially because few patients live long enough to develop definitive complications of iron overload.

Agents With Limited Efficacy

In the past, virtually every patient with MDS was given pyridoxine (vitamin B6), probably because of its safety and the fact that rare children with congenital dysmyelopoiesis may respond.[318] However, reports of adults who actually benefit are rare. Androgen therapy, formerly a mainstay in the treatment of patients with BM failure caused by aplastic anemia or myelodysplasia, is rarely used today because of the lack of supporting data and its untoward side effects.[319] Danazol is a weak androgen and possibly has immunosuppressive properties. Although danazol therapy occasionally improves anemia and thrombocytopenia,[320] the rarity of such responses and the associated side effects have led to abandonment of its typical use.

Immunosuppressive Therapy

For many years, patients with MDS were treated with steroids. Response rates in the 20% range were noted, but the increased use of prednisone in patients with myelodysplasia clearly led to more complications than benefit.[321] Nonetheless, several pieces of evidence have caused resurgence in enthusiasm for immunosuppressive therapy for MDS. First, autoimmune phenomena, often polyarthritis,[174] can be associated with MDS. Treatment with steroids in such cases may ameliorate the autoimmune manifestations and improve blood counts.[181] Patients with MDS have aberrant autoimmune hematopoietic inhibitory activity. In a subset of patients, clonal amplification of T lymphocytes has been demonstrated. The implication of this T-cell repertoire is that it suppresses hematopoiesis through a $CD8^+$ cytotoxic T-lymphocyte–mediated pathway.

Hypoplastic MDS bears morphologic similarity to aplastic anemia. Some patients with aplastic anemia who initially respond to immunosuppressive therapy may progress to MDS,[322] which suggests that these two entities share a common pathophysiology, that of T-cell–mediated suppression of a primitive BM stem cell. Indeed, antithymocyte globulin (ATG), the mainstay of nontransplant therapy for aplastic anemia,[323] has a role in certain patients with MDS. A report from the National Cancer Institute suggests that patients with MDS who are young and have low platelet counts may benefit from a trial of ATG, with response rates as high as 50%.[324] The pretreatment variables associated with a higher response to immunosuppressive therapy include younger age (<60 years) and short duration of RBC transfusion dependency (<6 months). Interestingly, findings have shown the presence of a PNH clone or the presence of human leukocyte antigen (HLA) DR15 phenotype is another predictor for response to ATG in MDS.[325] It was originally thought that only those patients with hypoplastic MDS would respond, but now it seems clear that BM hypoplasia is not a requirement for response, that rabbit or horse ATG can be used, and that patients with excess blasts rarely respond.[326]

Although no randomized trials have confirmed a survival benefit in patients treated with immunosuppressive therapy, a comparison of more than 800 patients in the IMRAW managed for prognostic variables showed that immunosuppressive therapy was associated with an improved overall survival time (8.1 vs. 5.2 years; $P < .001$).[116] Immunosuppressive therapy also was associated with a decreased risk of leukemic transformation ($P = .001$). The benefit in overall survival caused by decreased leukemic transformation was seen in patients with low and intermediate-1 IPSS who were younger than 60 years of age. In addition, investigators from Prague have shown that approximately 40% of patients with indolent subtype MDS may respond to cyclosporine A.[327] Although a large randomized trial testing the usefulness of ATG in MDS is ongoing, young patients with MDS who do not have excess BM blasts should be considered for a trial of immunosuppression.

Manipulating the Microenvironment

The pathophysiology of MDS is complex. However, it is increasingly recognized that the BM microenvironment, including endothelial cells, fibroblasts, and other stromal cells, as well as immune effector cells and certain elaborated cytokines may have critical roles in maintenance of the neoplastic MDS clone. For example, microvessel density is increased in the BM of patients with AML and MDS,[199] and proangiogenic substances such as vascular endothelial growth factor may be required for growth of neoplastic stem cells.[200] Second, at least in the indolent MDS subtypes, peripheral cytopenias in the presence of hypercellular BM have suggested overabundant apoptosis, perhaps because of stromal cell secretion of proapoptotic substances such as TNF.[62] Attempts to modify TNF availability with use of phosphodiesterase inhibitors such as pentoxyphylline in combination with the steroids and ciprofloxacin (pentoxyphylline, ciprofloxacin, and dexamethasone [PCD] therapy)[328] or with the direct anti-TNF molecule etanercept (Enbrel),[329] as used in rheumatoid arthritis,[61] have led to transient and low-level responses in MDS. Amifostine, a thiol-containing compound approved for use as a chemoprotectant and radioprotectant,[330] alone[331] or in combination with PCD,[332] has limited biologic activity, with clinical responses that are too rare to justify the routine use of any of these strategies without an ability to predict which patients will respond.

The proangiogeneic and proapoptotic cytokine milieu of MDS may be counteracted by agents such as thalidomide, which has been effective in treatment of patients with refractory myeloma.[294] Studies suggest that thalidomide can lead to a significant improvement in the need for transfusions in approximately 20% of patients with low-grade MDS subtypes.[333,334] However, many in the typical older patient population are poorly tolerant of the constipation, somnolence, and neuropathy typically associated with thalidomide use. The potent and better tolerated thalidomide analogue lenalidomide (Revimid), which has activity in patients with advanced multiple myeloma,[219,220,335] may well be a real advance in "microenvironment-directed" therapy in MDS. Arsenic trioxide, which is approved for use in relapsed acute promyelocytic leukemia[336] and may modify the cytokine and angiogenic milieu in MDS, has shown only limited clinical activity.[337,338]

Lenalidomide

Lenalidomide is a thalidomide derivative (CC5013) that has more potent inhibition of TNF-α and other inflammatory cytokines compared with the parent compound. In addition, lenalidomide has

greater capacity to promote T-cell activation and suppress angiogenesis. Importantly, lenalidomide lacks much of the neurotoxicity of thalidomide but still has myelosuppressive properties. A phase I study (MDS-001) was performed in patients with MDS who had symptomatic anemia and did not respond to treatment with ESAs.[220] Patients received doses of lenalidomide at 25 mg/day, 10 mg/day, or 10 mg/day for 21 days of a 28-day cycle, and 56% of patients experienced a durable erythroid response per the IWG. Twenty of 32 patients who previously were RBC transfusion dependent became independent of transfusion. Importantly, erythroid response rates were dependent on the presence of deletion of chromosome 5q, with 10 of 12 patients responding compared with 57% of patients with a normal karyotype and 12% of patients with abnormal karyotype. For patients with a 5q abnormality, responses were durable, with a median duration of major erythroid response exceeding 2 years. The dose-limiting toxicities were different than expected from thalidomide and predominantly included myelosuppression, specifically within the first month of therapy. In fact, grade 3 or greater neutropenia occurred in 58% of patients and grade 3 or greater thrombocytopenia in 50% of patients.

Two multicenter confirmatory trials were performed in patients with MDS and a low or intermediate-1 risk IPSS score. Patients were transfusion dependent and had not responded to an ESA. The MDS-002 study was performed in patients without a 5q abnormality, and lenalidomide was started at a dose of 10 mg/day or 10 mg/day on days 1 to 21 of a 28-day cycle.[339] The overall transfusion response rate was 43,% with 26% of patients achieving transfusion independence. The median duration of response was 41 weeks. Although only a minority of patients had clonal cytogenetic abnormalities 19% experienced a cytogenetic response. The principal toxicity remained myelosuppression, with 30% and 25% of patients developing grade 3 or greater neutropenia and thrombocytopenia, respectively.

A second phase II trial (MDS-003) was performed in transfusion-dependent patients with MDS who contained a deletion of chromosome 5q using a similar dosing regimen as in the MDS-002 study.[219] A total of 148 patients were enrolled, and erythroid responses were seen in 76% of patients, with an amazing 67% of patients achieving a transfusion-independent state. In addition, complete cytogenetic responses were seen in 73% of patients and partial cytogenetic responses in 45% of patients. Development of a cytogenetic response was associated with achievement of transfusion independence. Surprisingly, the presence of additional chromosomal abnormalities was not associated with a decreased erythroid or cytogenetic response rate. Myelosuppression was extremely common in patients with chromosome 5q abnormality, and grade 3 or greater neutropenia or thrombocytopenia was reported in 55% and 44% of patients, respectively. A retrospective analysis suggested that patients who experience a 50% reduction in platelet count or grade 3 myelosuppression during the first 8 weeks of therapy had a higher incidence of response compared to patients who did not have myelosuppression. Exogenous use of myeloid growth factors was effective in treatment-related neutropenia.

The long-term outcome of lenalidomide use for treatment of patients with MDS who harbinger a deletion of chromosome 5q has been analyzed.[340,341] The data confirm a long median duration of response of 2.2 years, with some patients responding for more than 5 years. Higher response rates were seen by multivariate analysis for patients with the "actual" 5q syndrome, RBC transfusions of fewer than 4 units per 8 weeks, low-risk IPSS score, and age younger than 70 years. Using Kaplan-Meier estimates, responders had a 10-year overall survival estimate of 78% compared with 4% for patients who failed to respond. Unfortunately, these data are retrospective but nevertheless suggest that lenalidomide may change the natural history of patients with MDS who concurrently have a chromosome 5 abnormality.

Differentiation Therapy

Can the putative block in normal hematopoietic differentiation in patients with MDS be reversed by pharmacologic agents? Many compounds, including the vitamin A analogue retinoic acid,[342] the protein kinase C inhibitors phorbol ester[343] and brysotatin,[344] polar-planar solvents such as phenylbutyrate[345] and hexamethylene bisacetamide,[346] and nucleoside analogues such as low-dose cytarabine (ara-C),[78] can promote maturation of leukemic cells in tissue culture. One of the first clinical efforts with one of these agents suggested that low-dose cytarabine produced responses in patients with MDS without causing aplasia.[347] Initial enthusiasm for low-dose cytarabine in MDS faded because of studies suggesting a low response rate in meta-analysis and that some of the responses really occurred because of hypoplasia, much as would be expected from standard chemotherapy.[348,349] A randomized trial conducted by the Medical Research Council demonstrated a superior overall survival compared with best supportive care in elderly patients with AML or high-risk MDS.[350]

A randomized trial of retinoic acid versus observation, one of the few such efforts in MDS, failed to show any discernible benefit for patients enrolled in the experimental arm.[351] Phase II clinical trials with phenylbutyrate[352] and hexamethylene bisacetamide[353] each produced a few impressive responses, but the low frequency of efficacy and the requirement for cumbersome prolonged infusions prevented major interest. Although not a differentiating agent, melphalan, an orally available alkylating agent, has produced complete remissions in limited testing in patients with MDS.[354]

The mechanism of retinoic acid's differentiation activity in acute promyelocytic leukemia is inhibition of histone deacetylase-mediated transcriptional repression engendered by the PML-RARA fusion protein consequent to the characteristic t(15;17) chromosomal abnormality.[355] Several compounds that, unlike retinoic acid, have direct histone deacetylase inhibitory capability are in development as potential therapeutic agents for MDS. Depsipeptide has undergone phase I testing in patients with AML.[356] The drug appears to be well tolerated and inhibits histone acetylation in vivo. Other histone deacetylase inhibitors, including phenylbutyrates, suberoylanilide hydroxamic acid (Vorinostat), valproic acid, MS-275, LAQ823, LBH589 (panobinostat), and MGCD0103, are undergoing phase I testing in patients with MDS and related disorders.[357,358] Not surprisingly, attempts have already been made to combine DNA hypomethylating agents with histone deacetylase inhibitors in the form of azacytidine plus phenylbutyrate[359] or decitabine plus valproic acid.[360] Such efforts require careful consideration of optimal scheduling and ample ancillary studies to determine if the presumed targets really are affected.

Hypomethylating Agents

Progress in the field of epigenetics,[361] including thoughts concerning promoting expression of transcriptionally silent genes that might be required for the differentiated phenotype, has rekindled interest in the use of small molecules to promote hematopoietic maturation in patients with MDS. Structural barriers to transcription result from either overmethylation of DNA[73] or underacetylation of the histone DNA coat.[362] Cells from patients with MDS typically display overmethylation of genes such as p15INK4B,[363] which argues in favor of the relevance of this mechanism.

The greatest recent therapeutic advance in the management of patients with MDS was highlighted by a phase III trial, albeit with early crossovers permitted, of the putative DNA hypomethylating agent azacytidine given subcutaneously daily for 7 days every 28 days versus observation in patients with MDS conducted by the Cancer and Leukemia Group B.[364] Randomization to azacytidine was associated with a response rate of 60% (mostly hematologic improvement), delay in transformation to AML, and improved quality of life measured by several validated instruments.[365] The benefit of azacytidine was apparent in patients with both high- and low-risk MDS; a trend toward improvement in overall survival in the azacytidine arm did not reach statistical significance. The side effect profile of the drug included mild nausea and vomiting and transient myelosuppression in some patients. Azacytidine, which now can be given intravenously, is metabolized in vivo to another hypomethylating agent decitabine.

Decitabine (5-aza-2′-deoxycytidine) has significant activity in patients with MDS based on a phase II trial performed in Europe[366] and a low-dose trial performed at the MD Anderson Cancer Center.[164] A phase III trial was performed in 170 patients with IPSS intermediate-1 or higher risk. Patients were randomized to receive either decitabine at a dose of 15 mg/m^2 given intravenously every 8 hours for 3 days or supportive care.[367] The overall response rate in patients treated with decitabine was 17%, including 9% complete remissions. Unfortunately, no effect was observed in terms of overall survival, but in a subgroup analysis, patients with intermediate-2 and high IPSS scores who received decitabine had a longer median time of progression to AML or death compared with patients who received supportive care alone (12.0 months vs. 6.8 months; $P = .03$). One of the difficult issues with this study is that 43 patients received only two cycles of therapy, yet more than two cycles or 3.3 months of therapy on average was required to demonstrate a clinical response. Both decitabine and azacytidine have been approved by the U.S. Food and Drug Administration and are being tested against supportive care in multi-institutional prospective phase III trials.

A randomized bayesian phase II trial of patients with MDS was conducted at the MD Anderson Cancer Center. Decitabine was administered in one of three schedules: 10 mg/m^2 intravenously for 10 days, 20 mg/m^2 intravenously for 5 days, or 20 mg/m^2 intravenously for 5 days.[368] All three groups of patients received the same total dose of decitabine, 100 mg/m^2. The 20 mg/m^2 intravenously for 5 days arm was preferentially enrolled, suggesting that this may be the superior regimen. The overall response rate was 48%, with 34% of patients entering a complete remission. Although these results seem to be superior to those achieved using the 3-day regimen, they must be confirmed in a multicenter trial.

Signal Transduction Inhibitors

In MDS subtypes associated with excess blasts, highly analogous to the situation in AML, the underlying biologic problem may include overproliferation or lack of apoptosis within the stem cell compartment. Insofar as there are patients with MDS whose disease behaves more like AML, one can think of the same therapies that are in use or in development for the more aggressive neoplasm. Moreover, older adults with AML in particular are generally presumed to have blasts that emanate from a primitive stem cell, similar to MDS.[97] As such, remission induction chemotherapy is a variable therapeutic alternative for some patients with MDS.

The constitutively activated tyrosine kinases BCR-ABL in CML[124] and FLT-3 in 30% of cases of AML[102] represent important drug targets. The development of imatinib for treatment of patients with CML[369] has revolutionized the treatment of patients with gastrointestinal stromal cell tumors based on the ability of imatinib to inhibit c-KIT,[370] idiopathic hypereosinophilic syndrome based on its ability to inhibit PDGFR-α.[371] Similarly, the rare patients with the MDS subtype CMML whose cells harbor a cytogenetic abnormality, such as t(5;12), a translocation that activates PDGFR-β,[226,227] also exhibit striking responses to imatinib.[183,227] Therefore, it is important to carefully scrutinize the cytogenetic results in patients with MDS, especially those with CMML, for any translocation involving the long arm of chromosome 5, for the potential of initiating imatinib therapy.

Several drugs that can inhibit the activated version of the FLT-3 tyrosine kinase are in development, particularly for use in AML.[372,373] However, rarely, and again probably more likely in CMML, patients with MDS may have one of two activating FLT-3 mutations, either a so-called *internal tandem duplication,* a copy of between 9 and 300 base pairs in the juxtamembrane region, or a mutation in the activation loop, usually a point mutation yielding a D835Y amino acid substitution.[102] As such, a few patients with primary MDS have been treated with PKC412, one of the FLT-3 inhibitors currently in clinical trials, and responses have been noted.[373] Identifying other tyrosine kinases that may be activated in MDS, and the drugs that inhibit them could yield future therapeutic advances.

Another cell-signaling therapeutic target in MDS is mutationally activated RAS, a 20-kd guanine nucleotide binding protein.[374] Because a mutation in a RAS family member occurs in approximately 20% to 40% of patients with MDS and most commonly in CMML, drugs that inhibit this enzyme are in development. The so-called *farnesyltransferase inhibitors* were developed because they inhibited an enzyme that catalyzed a key step in the posttranslational modification of RAS, preventing attachment of the farnesyl group required for movement to the cell membrane and enzyme activation.[375] Phase I and II trials with farnesyltransferase inhibitors have been completed in patients with MDS and AML.[376] One of the most important conclusions from these trials, in addition to the presence of only modest clinical activity, was that responses occurred exclusively in patients whose cells did not have RAS mutations, suggesting the likelihood of alternative targets, perhaps farnesylation of some of the many other proteins undergoing this posttranslational modification step, including lamin A or Ras homolog gene family B (RHOB).[377]

Induction Chemotherapy

Use of cytotoxic chemotherapy for treatment of patients with MDS was generally considered to be an unhelpful strategy based on the typically older age of these patients and their poor tolerance of chemotherapy. Moreover, the proximal nature of the stem cell defect in MDS suggests that patients would be resistant to chemotherapy, based on overexpression of proteins mediating pleiotropic drug resistance,[378] and would have limited normal stem reserve, making them prone to severe myelosuppression. However, Estey et al[379] demonstrated that patients with MDS can respond as well, or as poorly, to chemotherapy as those with AML if the key prognostic factors of age and cytogenetic status are controlled for. Complete response rates range from 40% to 50%. Unfortunately, these responses tend to be short lived, even with consolidation chemotherapy, which does support the intrinsic nature of chemotherapy resistance in MDS. Curative intensive consolidation regimens with high-dose ara-C is appropriate only for younger adults with de novo AML in first remission[380] and therefore has no role in the treatment of older patients with MDS, given that older adults with AML do not benefit from such an intensive approach.

The notion that selected patients with MDS might benefit from chemotherapy[379] was altered by the change in the definition of AML and MDS in the new WHO classification system. Patients with 20% or greater blasts, as opposed to 30% in the older FAB system, now are considered to have AML.[20] Second, patients with balanced chromosomal translocations associated with a favorable prognosis, such as inv(16), t(8;21), and t(15;17), are considered to have AML at any level of BM or peripheral blood leukemic cell involvement.[20] Applying the new definitions of MDS, relatively few patients are obvious chemotherapy candidates.

Induction chemotherapy may be useful in relatively younger patients with high-risk MDS, defined as greater than 10% blasts in the BM or with serious cytopenias. Such patients can be considered for nonmyeloablative or reduced-intensity conditioning allogeneic transplant.[381] Chemotherapy may be useful as a cytoreductive step before a reduced-intensity transplant, but prospective data are lacking. Although regimens containing topotecan alone or with ara-C[382] have activity in patients with MDS, this novel agent is no better than standard anthracycline and ara-C combination regimens[383] and should not be used routinely. Similarly, gemtuzumab ozogamicin, an antibody–toxin conjugate that is associated with a 30% remission rate in relapsed AML,[382] is expensive, myelosuppressive, and not particularly efficacious in patients with MDS.[384]

Stem Cell Transplantation

Recognition that the stem cell defect in MDS is proximal and pervasive suggested that allogeneic transplant would be required to eliminate the malignant clone, thereby making cure a possibility. Numerous

studies suggested that up to 60% of selected patients with low-risk MDS and 20% to 40% of patients with high-risk disease can experience long-term disease-free survival after allogeneic transplantation from a matched donor.[270,271,385-387] Albeit in a relatively young and well population, no other modality, including chemotherapy[379] or autologous BMT,[388] is associated with a similarly high success rate. Despite concern that high-dose chemotherapy with autologous BM or peripheral blood stem cell rescue would be an unworthy approach given that neoplastic stem cells would be difficult to eliminate in MDS and would grow poorly as an autograft, European investigators reported appreciable disease-free survival when this modality is used as consolidation therapy in MDS patients achieving remission with chemotherapy.[388] However, because these patients likely would be more typical of an AML population, autologous BMT still is considered an experimental procedure for MDS.

An important treatment decision concerns the appropriate timing of transplantation, especially in low-risk disease. Upfront SCT potentially can take advantage of relatively healthier BM, with waiting until disease progression delaying transplant-related morbidity. Cutler et al[389] analyzed a national database registry of transplant patients with MDS and their outcomes to perform a decision analysis addressing this question. They found that for low and intermediate-1 IPSS groups, delayed SCT was associated with better overall survival (Table 59-10). In contrast, for intermediate-2 and high IPSS groups, SCT at diagnosis maximized overall survival. The analysis focused only on full ablative conditioning regimens. Nevertheless, all patients with MDS who are reasonable transplant candidates based on age and comorbidity should undergo a formal consultation with transplantation specialist.

One clear advantage of allogeneic transplant in MDS, beyond the obvious benefit provided by the proffering of normal stem cells, is the powerful graft-versus-leukemia effect.[383] Evidence that neoplastic MDS cells are targets for killing by the graft emanates from data demonstrating a lower relapse after allogeneic, compared with syngeneic, transplants, the higher relapse rate after T-cell–depleted grafts, and mildGVHD.[390] The apparent safety of unrelated matched transplants has improved recently because of the advent and routine use of molecular HLA typing.[391] Although allogeneic transplant seems an attractive option, a major problem remains the mortality associated with regimen-related toxicity and GVHD, especially given the older age of the typical MDS patient. Use of nonmyeloablative or reduced-intensity conditioning, seeking to maximize the graft-versus-leukemia to toxicity ratio, is being used with increasing frequency.[381,392,393] Although it appears that reduced-intensity conditioning allogeneic transplantation can be accomplished with an acceptable short-term

Table 59-10 Decision Analysis of Allogeneic Bone Marrow Transplantation for Myelodysplastic Syndrome

International Prognostic Scoring System Category	Overall Survival (Years)		
	Immediate Transplant	*Transplant in 2 Years*	*Transplant at Progression*
Low	6.51	6.86	7.21
Intermediate-1	4.61	4.47	5.16
Intermediate-2	4.93	3.21	2.84
High	3.20	2.75	2.75

mortality rate in patients with MDS up to age 70 to 75 years, long-term data on efficacy are lacking.[394-396] Cord blood transplants could extend the availability of allogeneic transplantation to greater numbers of patients with MDS. This technique may prove feasible in older adults, especially if it is associated with an acceptable risk of GVHD.[397,398]

FUTURE DIRECTIONS

Despite recent advances in therapy for MDS, the need for improvement is great. Almost all patients with MDS should be referred for a clinical trial. Treatment recommendations involving available approaches and agents can be derived for a given patient but generally not without prolonged discussion between the physician and the patient and his or her family (Fig. 59-7). All patients younger than 70 years with high-risk disease according to the IPSS (intermediate-2 or high) and who have a related or unrelated matched donor should be considered for allogeneic BMT if feasible. Patients older than 55 years should consider reduced-intensity conditioning SCT, but the long-term efficacy data are lacking. Use of hypomethylating agents as a form of "cytoreduction" before SCT is being investigated. Patients with high-risk MDS who are not considered SCT candidates should initiate treatment with a hypomethylating agent such as azacytidine or decitabine. Patients with low-risk disease have many options. Patients with a chromosome 5q deletion or the 5q– syndrome who are RBC transfusion dependent should receive lenalidomide. Patients with low-risk disease who are RBC transfusion dependent and do not have a 5q abnormality have many options. If their serum EPO levels are less than 500 mU/mL, they should be started on an ESA, either rh-EPO or darbepoetin. If this treatment fails, then addition of a myeloid growth factor, such as G-CSF, should be considered. ATG should be considered for treatment of hypoplastic MDS in patients younger than 60 years who have modest transfusion requirements, a recent diagnosis, and a low blast count. Nonresponding patients with low-risk disease should consider lenalidomide if the goal is only an erythroid response, or a hypomethylating agent should be considered in patients with pancytopenia. Clinical trial participation should be considered for all patients because this is the only way that we can try to make strides in improving the survival of patients with MDS.

CHAPTER 60

ALLOGENEIC HEMATOPOIETIC STEM CELL TRANSPLANTATION FOR ACUTE MYELOID LEUKEMIA AND MYELODYSPLASTIC SYNDROME IN ADULTS

John Koreth, Joseph H. Antin, and Corey Cutler

Recent advances in molecular diagnostics are shedding considerable light on genetic underpinnings of myelodysplastic syndrome (MDS) and acute myeloid leukemia (AML). However, with notable exceptions both diseases remain therapeutic challenges. Fortunately, our ability to provide more precise prognostic information has corresponded with advances in transplantation technology. We are increasingly able to apply transplantation to older people and those with comorbidities and to use alternative donors in patients without matched family members. By applying molecular prognostic criteria we can provide transplantation to patients with poor outcomes on conventional therapy and we can avoid transplant-related toxicity in those patients who are likely to do well with supportive care or nontransplant therapy.

Allogeneic hematopoietic stem cell transplantation (HSCT) is curative in MDS and AML due to a combination of the cytotoxicity of the preparative conditioning regimen and the donor-mediated immunologic graft-versus-leukemia (GVL) effect. Regimen intensity ranges from high-dose myeloablative conditioning (MAC) that induces profound and prolonged pancytopenia to reduced-intensity conditioning (RIC) that induces milder cytopenias and is more appropriate for older patients and those with comorbidities in whom MAC may be intolerable. The risk-benefit ratio of conditioning regimen intensity varies with factors like patient age, comorbidities, and relapse risk. In general, more intense regimens cause more treatment-related morbidity and mortality but are associated with a lower relapse rate. Conversely, there are more relapses in RIC HSCT, but the procedure is more tolerable.[1]

ACUTE MYELOID LEUKEMIA

AML displays considerable clinical heterogeneity with markedly variable survival, traditionally defined by prognostic factors of patient age, blast morphology, white blood cell count, prior MDS or cytotoxic therapy, remission status, and karyotype, but increasingly further refined by novel molecular markers. In addition to a burgeoning number of new prognostic indicators, there are now novel AML therapeutic agents in clinical trials, which also constitute an alternative to usual cytotoxic chemotherapy.

However, AML also constitutes the leading indication for HSCT worldwide, accounting for 7026 of 21,516 allogeneic HSCT (33%) in 2006.[2,3] Moreover, the use of molecular tissue typing in conjunction with better control of treatment-related complications has increased the use of alternative donors. Data from the Center for International Blood and Marrow Transplant Research (CIBMTR) indicate that 1286 of 1778 allogeneic HSCT (72%) undertaken for AML in 1998 involved related donors, compared to 1223 of 2557 allogeneic HSCT (48%) in 2008. In contrast, the number of unrelated donor HSCT for adult AML increased from 297 in 1998 to 1017 in 2008, while the number of umbilical cord blood (UCB) transplantations increased from 11 to 130 over the same time period.[4] It is likely that the ability to use donors that are not histocompatible will further increase the pool of patients in whom HSCT is an effective therapy.[5]

Matched Related Donor HSCT for Adult Acute Myeloid Leukemia in First Complete Remission

Cytogenetics is the most powerful prognostic indicator in AML, both at the time of diagnosis and at relapse, and can also direct choice of curative postremission therapy, especially for adult patients less than 60 years of age.[6,7] Adult AML patients can be stratified into good-risk, intermediate-risk, and poor-risk groups on the basis of numeric and/or structural chromosomal abnormalities and the presence of specific mutations (see Chapter 58).

Numerous groups prospectively evaluated the relative benefits of allogeneic HSCT versus nonallogeneic therapies (consolidation chemotherapy or autologous HSCT) in adult AML patients 18 to 60 years of age in first complete remission (CR1). Treatment allocation was by biologic assignment as a surrogate for true randomization, with allogeneic HSCT for patients with available human leukocyte antigen (HLA)–matched sibling donors (donor group) and nonallogeneic consolidation for those lacking matched sibling donors (no-donor group). Some of these studies further stratified postremission outcomes by cytogenetic risk. Individual studies, when analyzed on an intent-to-treat (ITT) donor versus no-donor basis, typically demonstrated that allogeneic HSCT was effective at improving disease-free survival, but overall survival benefit was hard to document because of graft-versus-host disease (GVHD) and other treatment-related mortality.

In an effort to overcome some of the limitations of individual trials, a recent meta-analysis of over 6000 patients in 24 biologic treatment assignment trials was undertaken. This study confirmed that overall survival was in fact better in allogeneic matched related donor transplantation in AML-CR1, with a hazard ratio (HR) of death at 0.90 (95% confidence interval [CI], 0.82 to 0.97).[8] Importantly, when stratified by cytogenetic risk, there was an overall survival benefit of allogeneic transplantation (Table 60-1) for both intermediate-risk (HR, 0.83; 95% CI, 0.74 to 0.93) and poor-risk (HR, 0.73; 95% CI, 0.59 to 0.90) cytogenetic groups, but not for good-risk AML-CR1 (HR, 1.07; 95% CI, 0.83 to 1.38) (Fig. 60-1). These findings were particularly relevant for patients with normal cytogenetic AML, who constitute the largest subgroup and for whom no consensus regarding optimal postremission treatment was previously available. These studies did not have the benefit of prognostic assignment based on FLT3, NPM1, or other molecular markers.

Prognostic Factors for Acute Myeloid Leukemia in First Complete Remission

Good-Risk Acute Myeloid Leukemia

In general, the 15% to 20% of AML patients with core binding factor (CBF) leukemia—t(8;21) (q22;q22) and inv(16)(p13.q22)—are considered to have good-risk disease, with a long-term disease-free survival of approximately 50% to 60% after consolidation chemotherapy. However, retrospective studies have identified activating

Table 60-1 Allogeneic Transplantation Guidelines for Adult Acute Myeloid Leukemia

AML Category	Prognostic Impact	Allogeneic Transplantation	Notes
AML-CR1: younger adults			
Good-risk disease			
APL	Favorable	No	APL is treatable by chemotherapy
CBF-AML without mKIT	Favorable	No	t(8;21) AML with high WBC count at diagnosis may have worse prognosis
CBF-AML with mKIT	Unfavorable	Possible: MRD, MUD Uncertain: MMUD, UCB, haplo	
Intermediate-risk disease			
CN-AML with CEBPA	Favorable	No	Benefit likely restricted to DM-CEBPA
CN-AML with NPM1 but not FLT-3-ITD	Favorable	No	
Other intermediate-risk disease	Unfavorable	Yes: MRD Likely acceptable*: MUD Possible†: MMUD, UCB, haplo	
Poor-risk disease			
Monosomal karyotype absent	Unfavorable	Yes: MRD, MUD Likely acceptable†: MMUD, UCB, haplo	
Monosomal karyotype present	Very unfavorable	Yes: MRD, MUD. Acceptable†: MMUD, UCB, haplo	
AML-CR1: older adults	Unfavorable	Yes: MRD, MUD Likely acceptable†: MMUD, UCB	
AML-CR1: t-AML, AML/MDS	Unfavorable	Yes: MRD, MUD Acceptable†: MMUD, UCB, haplo	
AML-CR2	Very unfavorable	Yes: MRD, MUD Acceptable†: MMUD, UCB, haplo	
AML not in remission	Very unfavorable	Yes: MRD, MUD Uncertain: MMUD, UCB, haplo	For selected patients: good performance status, little comorbidity, lower leukemic burden; CIBMTR risk score may be useful

mutations in C-KIT (mKIT)—a member of the type III receptor tyrosine kinase family—at exon 17 (mKIT 17) or exon 8 (mKIT 8) in approximately 30% of CBF AMLs that are associated with increased relapse incidence and likely poorer survival, though results from individual studies vary.[9,10] For instance, in an analysis of 61 patients with inv(16), mKIT was associated with 5-year relapse rate of 56% compared with 29% ($P = 0.05$) without mKIT mutations. This effect is especially prominent with mKIT17, where 80% relapsed compared with 29% without the mutation ($P = 0.002$). Similarly, in 49 patients with t(8;21), the 5-year relapse rate was 70% in the presence of mKIT mutations compared with 36% with wild-type mKIT ($P = 0.017$). These relapse rates are similar to that of poor-risk AML, suggesting a potential benefit of allogeneic HSCT in this subset.

Intermediate-Risk Acute Myeloid Leukemia

The intermediate-risk cytogenetic group is heterogeneous and includes cytogenetically normal disease as well as those with karyotypic abnormalities not meeting criteria for good- or poor-risk AML. It constitutes the largest risk category, accounting for approximately 40% to 50% of adult AML patients less than 60 years of age. Long-term disease-free survival of approximately 40% to 45% is anticipated after consolidation chemotherapy. However, identification of mutations with prognostic importance such as mutant FLT3 internal tandem duplication (ITD), NPM1, and CEBPA (CCAAT/enhancer binding protein-α) can help further individualize the decision regarding allogeneic transplantation.

Patients with FLT3-ITD have inferior survivals compared to those without FLT3-ITD.[11,12] The negative impact of FLT3-ITD appeared abrogated by allogeneic transplantation in CR1 when assessed on an ITT donor versus no-donor basis, although in this analysis the patients were not preferentially assigned transplantation on this basis. The finding of allogeneic transplantation benefit therefore remains to be prospectively validated. The nucleophosmin 1 (NPM1) and CEBPA mutations are associated with good outcomes independent of HSCT, and most investigators do not offer HSCT in first remission.[11,13-15] The favorable impact of NPM1 mutations appears to persist even in older patients.[16] There is a growing list of additional prognostic markers undergoing evaluation in AML. These include

mutation analysis of RAS, WT1, RUNX1, MLL, TET2, IDH1/2, p53; expression levels of individual genes like EVI1, ERG, MN1, and BAALC; and gene expression and micro–ribonucleic acid (miRNA) profiling.[6,11,17] Many mutations appear to be linked with poorer outcomes (e.g., EVI1, MLL, IDH1/2, p53), although some (e.g., TET2, RAS) appear to not have a significant impact on survival. Low expression levels of BAALC, ERG, and possibly WT1 appear associated with better AML outcomes. It is important to integrate the gene mutation and expression markers to better assess their overall impact in AML clinical management. If validated, such analyses highlight the ability of carefully selected novel markers to further delineate prognosis within intermediate-risk AML. This suggests that this category of risk will gradually disappear as prognostic precision improves. Although the better-prognosis subgroup within intermediate-risk AML may not benefit from early allogeneic transplantation, it appears to be the preferred postremission therapy for intermediate-risk AML patients at higher risk for relapse, including those lacking favorable gene mutations like NPM1 without FLT3-ITD, or mutant CEBPA.

Poor-Risk Acute Myeloid Leukemia

In poor-risk AML relapse rates are high and survival rates are anticipated to be 15% or lower with conventional consolidation therapy. Allogeneic HSCT with a matched sibling or unrelated donor results in long-term survival of 30% to 40% and is considered the treatment of choice for younger adults aged less than 60 years of age with poor-risk AML. There is, however, a subgroup of poor-risk AML that may have particularly adverse prognosis, for whom additional novel therapeutic strategies may be necessary.

The monosomal karyotype (MK) is defined by the presence of a single autosomal monosomy, in association with at least one additional monosomy or non–good risk structural chromosomal abnormality (i.e., excluding CBF mutation AML).[18] In the original report, MK-positive AML patients had a long-term survival of only 3% to 4%, and these generally dismal chemotherapeutic outcomes have been confirmed by other investigators.[19] Allogeneic transplantation appears to only partly ameliorate the impact of MK-positive karyotype, which remained an adverse prognostic factor after HSCT, and was associated with a high relapse risk of 62% at 4 years.[20] Improving outcomes in MK-positive AML must be a high priority for improving AML survival.

Transplantation Regimen Intensity

Myeloablative HSCT remains the standard of care for younger adults with AML. However, treatment-related mortality after MAC remains appreciable, especially in older patients or those with comorbidities. Lower-intensity regimens offering less treatment-related toxicity are gaining in popularity. One report retrospectively compared RIC transplantation with chemotherapy in high-risk AML on a donor

versus no-donor basis. They identified a leukemia-free survival benefit in the donor group (54% versus 30%, $P = 0.01$).[21] Several groups have compared MAC versus RIC transplantation, documenting similar overall and leukemia-free survival, with some reporting lower treatment-related mortality offset by increased relapse risk, especially for patients not in complete remission at time of HSCT. A recent CIBMTR study compared 3731 MAC, 1041 RIC, and 407 nonmyeloablative transplantations, reporting adjusted 5-year overall survivals of 34%, 33%, and 26%, respectively.[22] The authors concluded that, although nonmyeloablative transplantation had increased relapse and impaired survival, RIC and MAC regimens had similar overall and leukemia-free survival. A prospective randomized trial of MAC versus RIC transplantation in AML-CR1 patients greater than 40 years of age is underway in the Blood and Marrow Transplantation Clinical Trials Network to validate these findings. If confirmed, RIC transplantation might represent a new standard of care, especially in older or sicker AML-CR patients for whom the toxicity of MAC transplantation might be prejudicial. Conversely, patients with good performance status but high AML relapse risk might be preferentially selected for MAC.

Alternative Donor Transplantation

HSCT from an HLA-matched sibling donor has been the standard of care for prospective biologic treatment assignment studies evaluating postremission therapies. Patients lacking sibling donors could be considered for alternative donors: unrelated adult donors, UCB, or haploidentical donor transplantation.

Unrelated Adult Donors

Given the very poor outcomes after nonallogeneic therapy in poor-risk AML, and the documented benefit of HLA-matched sibling donor HSCT, clinical practice has been to undertake HLA-matched unrelated donor transplantation for younger adults with poor-risk AML in CR1 who lack sibling donors. A retrospective analysis of HLA-matched sibling compared with unrelated donor HSCT in poor-risk AML-CR1 documented comparable outcomes with HLA-matched siblings and HLA well-matched unrelated donors with 3-year overall survival of 45% compared with 53% ($P = 0.63$).[23] Outcomes were not as good for partially HLA-mismatched unrelated donors (one-locus HLA mismatch), with 3-year overall survival of 31% ($P = 0.026$). Smaller prospective studies have also shown equivalent results, confirming the suitability of well-matched unrelated donor HSCT in poor-risk AML.[24,25]

There is limited data comparing HLA-matched sibling with unrelated donors in intermediate-risk AML, although at least one study documented similar outcomes with either donor type.[26] Current practice is to offer HLA-matched unrelated donor HSCT to intermediate-risk AML patients in first remission, especially if there are adverse molecular lesions.

Umbilical Cord Blood

Another important issue is the use of UCB transplantation for AML in CR1. These data are harder to interpret because most studies have reported outcomes for "acute leukemia," rather than restricted to AML-CR1. A European registry study documented similar outcomes of UCB versus unrelated donor bone marrow (BM) transplantation in adults with acute leukemia, whereas a contemporaneous CIBMTR study showed better outcomes with HLA-matched unrelated donor BM transplantation, but similar outcomes of UCB and HLA-mismatched unrelated donor BM transplantation.[27,28] A recent large analysis of adult acute leukemia (including 880 AML patients) compared the outcomes of single-unit 4-6/6 HLA-matched (HLA-A, -B, -DRB1) UCB with 8/8 or 7/8 HLA-matched (HLA-A, -B, -C, DRB1) BM or peripheral blood stem cell (PBSC) transplantation and documented similar leukemia-free survival regardless of stem cell source or degree of HLA match. There was higher treatment-related mortality after UCB transplantation.[29] Transplantation in CR1 resulted in similar 2-year leukemia-free survivals of 44%, 50%, 52%, 39%, and 41% with UCB, 8/8 PBSC, 8/8 BM, 7/8 PBSC, and 7/8 BM transplantation, respectively. In contrast, a Japanese study evaluated outcomes of 484 AML patients receiving 4-6/6 UCB compared with 8/8 unrelated donor BM transplantation and documented a similar relapse risk with UCB transplantation, but higher treatment-related mortality and worse overall and leukemia-free survival.[30]

Double-unit UCB (DUCB) transplantation is commonly used for larger patients. Indeed, since 2005 the number of adults receiving DUCB has exceeded those receiving single-unit UCB products. Limited data suggest similar outcomes of myeloablative DUCB, HLA-matched unrelated, and sibling donor HSCT in hematologic malignancies.[31] However, only a subset of patients had AML. The role of DUCB in AML remains to be better demarcated. In general however, current clinical practice envisages use of UCB transplantation in younger adults with high-risk AML in CR1 who lack suitable HLA-matched donors.

Haploidentical Donors

There are no studies of haploidentical transplantation that allow a precise recommendation for patients with AML. Several strategies have been used in high-risk patients, and the outcomes are encouraging.[5,32-34] Haploidentical transplantation is particularly interesting given the potential enhancement of GVL activity by natural killer cells and allogeneic T cells responding to the HLA disparity.

Relapsed, Refractory, and Induction-Failure Acute Myeloid Leukemia

Outcomes are impaired for AML patients not in remission at the time of allogeneic HSCT, although the literature in this regard is limited, heterogeneous, and likely subject to patient selection and publication bias. A large analysis of MAC HSCT for acute leukemia in relapse or in primary induction failure (including 1673 AML patients) documented a 3-year overall survival of 19% in AML.[35] On multivariable analysis, risk factors at time of HSCT of poor-risk cytogenetic AML, CR1 duration of less than 6 months, circulating AML blasts, performance score of less than 90%, and lack of an HLA-matched sibling donor predicted for 3-year survivals ranging between 42% (zero risk factors) and 6% (three or more risk factors). The major cause of death remains AML relapse, and innovative strategies to reduce leukemic burden before transplantation and enhance GVL effect after transplantation are required to improve survival of this extremely high-risk patient population.[36] The ability to rapidly proceed to allogeneic transplantation may also be important given the dismal outcome of chemotherapy alone, suggesting a role for expeditious UCB and haploidentical BM transplantation in this setting, especially for patients achieving a remission.

Therapy-Related Acute Myeloid Leukemia

Therapy-related AML (t-AML) currently accounts for approximately 10% to 20% of newly diagnosed AML, and its incidence is likely to rise in the future, given increasing cancer survivorship. Postremission therapy using conventional chemotherapy is usually not curative with the rare exception of CBF-AML, specifically inv(16) and t(15;17). Allogeneic HSCT is less effective in t-AML and in AML arising from antecedent MDS. The poorer survival appears multifactorial, due to poor-risk cytogenetics, lower likelihood of entering remission, older patient age, and impaired organ function from prior cancer therapy; although some reports documented similar posttransplantation survival compared to de-novo AML when adjusted for risk factors like disease status and cytogenetics.[4,37] An

observational analysis of 545 patients with t-AML identified four risk factors influencing HSCT outcomes: age greater than 35 years, poor-risk cytogenetics, AML not in remission, and lack of well-matched donors. A prognostic score could stratify outcomes from 5-year overall survivals of 50% (zero risk factors) to 4% (four risk factors).[38]

Acute Myeloid Leukemia in Older Adults

AML incidence rises with age, with a median age at diagnosis of 67 years (Surveillance, Epidemiology and End Results data: http://seer.cancer.gov/). For AML patients older than 60 years, consolidation chemotherapy is unlikely to be curative (Fig. 60-2). Even after adjusting for increased incidence of poor prognosis features like adverse cytogenetics, secondary AML, and poorer performance status, older age remains an independent predictor of poor survival with conventional chemotherapy. Although allogeneic HSCT is a curative therapy in the older age-group, there is considerable reluctance to refer these patients for transplantation, in contrast to younger adults with AML, in part due to outdated assumptions regarding the tolerability of allogeneic transplantation, but also due to lack of comparative data regarding outcomes.

Several reports have documented the feasibility of RIC transplantation with acceptable toxicity and reasonable survival in patients 60 years of age and above, including those with AML. Indeed, chronologic age alone does not appear to be a prognostic factor in RIC allogeneic transplantation for AML.[39,40] In a case-control study comparing RIC transplantation with chemotherapy for AML patients 60 to 70 years of age, allogeneic HSCT was associated with lower relapse risk (32% versus 81%, $P < 0.001$), greater treatment-related mortality (36% versus 4%; $P < 0.001$), and longer 3-year leukemia-free survival (32% versus 15%, $P = 0.001$), with a borderline 3-year overall survival benefit (37% versus 25%, $P = 0.08$).[41]

Overall, for physically fit older AML patients, especially those between 60 and 70 years of age, a donor search should be undertaken promptly at diagnosis, and they should be offered the option of potentially curative allogeneic transplantation upon entering complete remission.

Relapse After Transplantation

AML relapse after allogeneic transplantation is common, has a very poor prognosis, and remains a leading cause of death in this disease. The treatment recommendations for patients with disease relapse after HSCT include withdrawal of immune suppression, donor lymphocyte infusion (DLI), chemotherapy, second allogeneic transplantation, or supportive care.[42] Taper of immune suppression and DLI are used especially in patients without GVHD. DLI has limited efficacy, in the range of 15% to 30%, for patients with relapsed AML, and many responses are incomplete or temporary. Outcomes are better in patients who relapsed beyond 6 months after HSCT, those with lower leukemic burden (less than 35% bone marrow blasts), patients with good-risk cytogenetics, and those who achieved remission before DLI.[43] A second allogeneic HSCT has demonstrable but limited efficacy, and duration of remission of more than a year after initial HSCT is the major predictor of survival.[44]

TRANSPLANTATION FOR MYELODYSPLASTIC SYNDROME

The MDSs comprise a heterogeneous group of clonal hematologic stem cell disorders characterized by varying degree of cytopenias and risk for transformation into acute leukemia[45] (see Chapter 59). The incidence and prevalence of MDS has increased significantly over the last 20 years as a result of increasing longevity of the population and increasing physician awareness.[46-48] New therapeutic options such as hypomethylating agents, immunomodulatory drugs, and differentiation induction agents may improve hematologic parameters and reduce transfusion requirements,[49] and even prolong survival,[50] but allogeneic HSCT is the only known curative therapeutic option.

MDS is currently the third most common indication for allogeneic HSCT as reported to the CIBMTR.[3] MDS is a disease predominantly of older individuals, and with the increased use and acceptance of RIC into the eighth decade of life, it is anticipated that transplantation volume for MDS will continue to increase in the coming years.

Clinical Results in Myeloablative Transplantation

There are few reports of transplantation uniquely for patients with the myelodysplastic disorders, because most reports include both patients with AML and those with MDS. Those few analyses that do exist unfortunately often present biased results, because there is inherent patient selection in the reported studies. The bias in these analyses, although recognized by physicians and patients alike, is often overlooked, because patients who choose early HSCT often identify with those included in the analysis to justify their decision.

One of the largest reports of MAC HSCT for MDS is from the Seattle group. Using a targeted busulfan strategy in patients undergoing related or unrelated donor HSCT, results were presented stratified by pretransplant International Prognostic Scoring System (IPSS; see Chapter 59) risk score.[51,52] Patients were prospectively enrolled in the targeted busulfan treatment program; however, the decision to undergo transplantation was based upon physician and patient preference. Results in this study were correlated with IPSS stage, suggesting that outcomes were improved with HSCT at an earlier disease stage. This would be expected, because patients with earlier-stage disease have had less treatment for their disease (thus less comorbidity) and may also have more indolent disease biology. Among the patients in the lowest IPSS score group there were no relapses, whereas

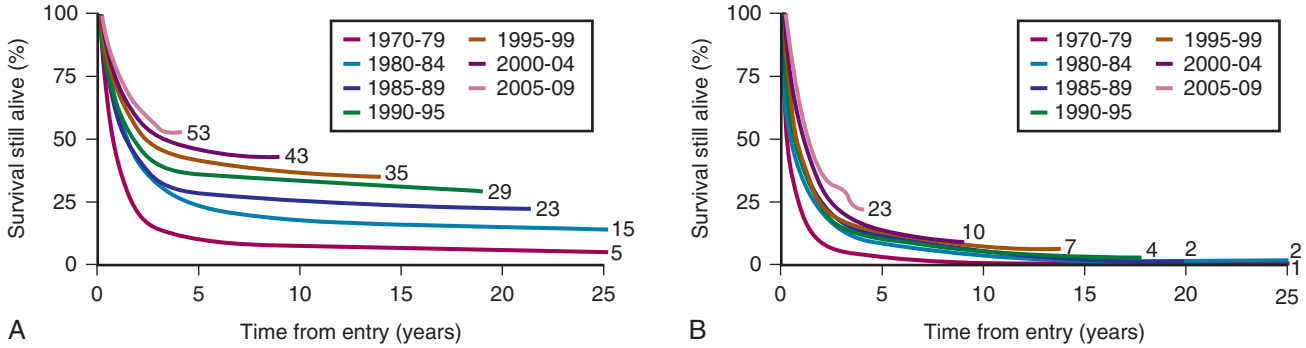

Figure 60-2 CHANGE IN ACUTE MYELOID LEUKEMIA OVERALL SURVIVAL WITH TIME. **A,** Age 15 to 59 years. **B,** Age 60 years or greater. *(Data from Burnett A, Wetzler M, Lowenberg B: Therapeutic advances in acute myeloid leukemia,* J Clin Oncol *29:487, 2011.)*

the relapse rate was 42% for patients in the highest IPSS category. As a consequence, 3-year survival was 80% in the lowest IPSS risk group but was under 30% for patients in the high IPSS category.

Similarly, de Witte et al[53] examined outcomes of HSCT for patients with earlier-stage MDS (refractory anemia or refractory anemia and ringed sideroblasts). This analysis studied 374 patients who underwent HSCT from either matched, sibling, or unrelated donors. Both standard MAC and RIC regimens were used. IPSS score could be calculated in fewer than half of the patients, and HSCTs were performed over a decade-long period, such that inherent differences in transplantation technology resulted in improved overall survival over time. Although factors such as conditioning intensity, stem cell source, and donor status did not affect outcome, recipient age and duration of identified MDS diagnosis were important predictors of overall survival. Earlier transplantation was associated with an absolute increase in overall survival of 10% at 4 years (57% versus 47%, $P = 0.02$) and was associated with improved relapse-free survival in multivariable analysis. Despite the finding of improved outcome with earlier HSCT, this should not be interpreted as a recommendation for early HSCT in individuals with low-risk MDS, because the authors did not compare outcomes to a cohort of patients treated with supportive care alone.

Clinical Results in Reduced-Intensity Conditioning Transplantation

It appears that late relapses after MAC HSCT are not common,[54] but high-intensity regimens are associated with higher treatment-related mortality.[55] Thus many groups have moved toward a reduction in conditioning intensity.

Previously HSCT was available to only a minority of patients with MDS, because 75% of patients are older than 60 years at diagnosis and are not candidates for MAC regimens. Because older patients have a poorer prognosis than their younger counterparts, there is a great impetus to develop strategies for older individuals. Within the RIC literature, there is great variability in the reported conditioning intensity; however, the commonality of these regimens is that they can be safely offered to patients previously deemed to be too old or to have too much comorbidity for high-dose therapy.

The City of Hope group has reported on their outcomes using a RIC regimen of fludarabine and melphalan in 43 patients with MDS or AML. Overall survival was 53% at 2 years, with a 16% relapse rate.[56] Treating over 90 patients with AML (n = 74) or AML (n = 22) using a targeted busulfan and fludarabine regimen, de Lima et al[57] reported 1-year treatment-related mortality of only 3%, without a compromise in antitumor activity. Using this more commonly applied RIC regimen of fludarabine with busulfan, albeit with different intensities (and including some patients with AML), other groups have demonstrated similar outcomes, with treatment-related mortality of 13% to 27%, relapse rates of 23% to 32%, disease-free survival of 38% to 68%, and overall survival of 39% to 79%.[58-61]

With the increased acceptance of RIC preparative regimens, and the resultant reduction in treatment-related mortality, determination of the optimal timing of HSCT will be critical.

Comparative Results: Myeloablative and Reduced-Intensity Regimens in Myelodysplastic Syndrome

Several analyses have compared RIC with conventional MAC transplantation, and the majority of them suggest similar outcomes. The premise behind all of these comparisons is that RIC should be associated with a reduction in early treatment-related mortality, whereas MAC approaches should be associated with a reduction in disease relapse. The net effect of these two opposing risks is no difference in outcomes. For example, at the Dana-Farber Cancer Institute, the outcomes of 136 patients with advanced MDS or acute myelogenous leukemia who underwent transplantation were compared when stratified by conditioning regimen intensity.[1] Overall survival at 2 years was the same following RIC as for MAC transplantation (28% versus 34%, $P = 0.89$); however, the causes of treatment failure were significantly different, with more relapse in the RIC group (61% versus 38%, $P = 0.02$), but higher treatment-related mortality in the MAC group (32% versus 15% at 100 days) as anticipated. Overall treatment-related mortality, however, was no different ($P = 0.28$). In this report, patients were treated according to patient and physician preference, whereas in a similar single-center analysis reported by Martino et al,[62] patients were prospectively assigned to RIC or $CD34^+$ selected MAC transplantation based on patient age. In this analysis, nonrelapse mortality and overall survival were no different between groups.

Similar to single-center studies, large retrospective database studies comparing RIC and high-intensity HSCT have been performed. A CIBMTR review of the outcomes of 550 patients 50 years of age or older who underwent matched sibling donor HSCT showed no difference in MAC and RIC outcomes.[3] In an even larger CIBMTR analysis that included both patients with MDS and those with AML, patients were stratified into MAC, RIC, and truly nonmyeloablative subgroups. Although results for MDS alone are not available, overall outcomes indicated less-favorable long-term results for nonmyeloablative regimens when compared with higher-intensity regimens.[22] In an analysis by the European Group for Blood and Marrow Transplantation (EBMT) of over 800 patients with MDS, the 3-year relapse rate was significantly higher after RIC (HR, 1.64; $P = .001$), but with less treatment-related mortality (HR, 0.61; $P = .015$), leading to similar 3-year overall survival (45% versus 41%, $P = 0.8$). When limited to individuals above 50 years of age, no difference in outcome stratified by conditioning intensity (32% versus 30%, $P = 0.73$) was noted.[63] Competing risk cumulative incidences for relapse and nonrelapse mortality are shown in Fig. 60-3.

It is important to consider that none of these retrospective studies adjusted for comorbidity, and it is almost certain that if reanalyzed, the RIC cohorts would contain a higher proportion of patients with more comorbid conditions. Because only a minority of studies have suggested that regimen intensity is important for long-term outcomes, some patients have now opted for earlier RIC transplantation, even without comorbidity, because treatment-related morbidity and mortality after this procedure is lower than after traditional MAC transplantation. In order to compare outcomes prospectively among patients eligible to undergo both MAC and RIC transplantation, the Bone Marrow Transplant Clinical Trials Network has embarked upon a randomized, controlled trial in patients 18 to 65 years of age.

Using Prognostic Models to Define the Role and Timing of Transplantation

Clinical, Laboratory, and Cytogenetic Prognostic Factors

Comparative registry analyses have documented the benefit of HSCT over conventional supportive and disease-modifying agents in MDS[64]; however, this should not be interpreted as an indication for HSCT in all patients. Despite the curative potential of HSCT, transplantation carries substantial risk for early morbidity and mortality, and careful consideration must be made regarding the appropriateness of each potential recipient and the timing at which transplantation is offered. Despite this, all patients who are potential candidates for HSCT should be referred to a transplantation center early in their disease course so that a discussion regarding the appropriateness of transplantation can occur and a donor search can be initiated, where appropriate. The correct timing of HSCT is therefore of paramount importance, and decisions regarding the timing of HSCT should be made on more than patient preference alone.

The most widely used clinical prognostic system is the IPSS. Not only does this combined clinical and laboratory scoring system predict nontransplantation outcomes, but the IPSS at the time of HSCT can predict MAC outcomes as well.[65,66] A Markov decision

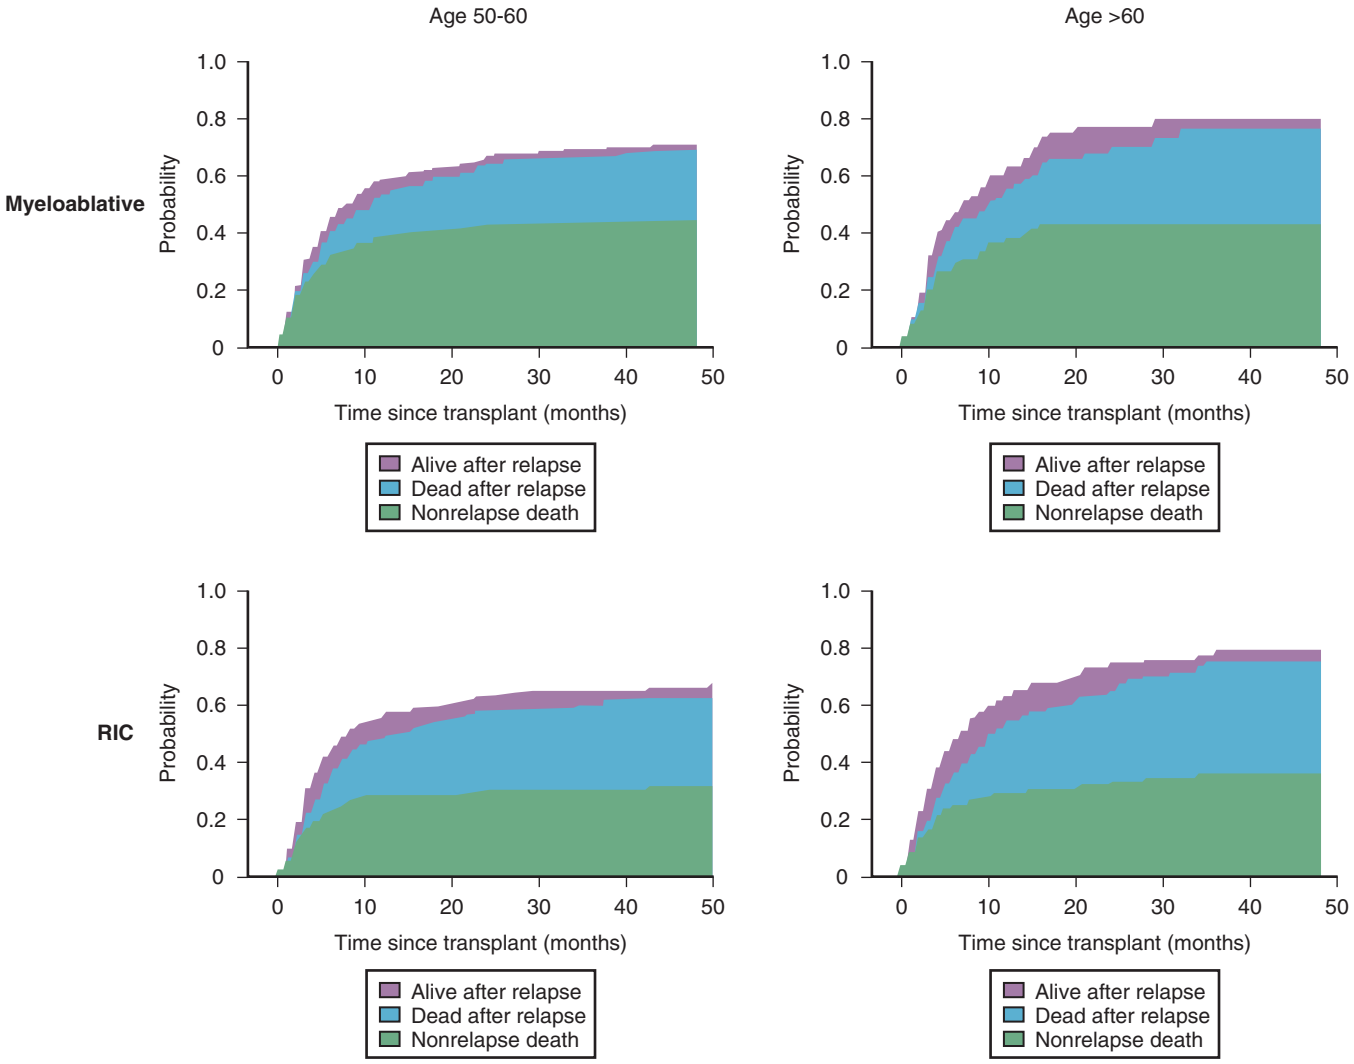

Figure 60-3 COMPETING RISK CUMULATIVE INCIDENCES FOR RELAPSE AND NONRELAPSE MORTALITY AMONG INDIVIDUALS ABOVE AGE 50 YEARS. *RIC,* Reduced-intensity conditioning. *(Data from Lim Z, Brand R, Martino R, et al: Allogeneic hematopoietic stem-cell transplantation for patients 50 years or older with myelodysplastic syndromes or secondary acute myeloid leukemia,* J Clin Oncol *28:405, 2010.)*

model can help determine if HSCT at the time of initial diagnosis, delayed a fixed number of years, or at the time of leukemic transformation is the optimal strategy when IPSS score at the time of diagnosis is considered. Data from several large, nonoverlapping databases demonstrated that the optimal treatment strategy for patients with low and intermediate-1 IPSS disease was to delay transplantation until the time of leukemic progression. Immediate transplantation was recommended for patients with intermediate-2 and high-risk IPSS scores, even when adjustment for quality of life was considered.[65]

A shortcoming of this analysis was the inability to provide treatment decision guidance at other clinically relevant times for patients not undergoing immediate HSCT, because other important clinical events, such as a new transfusion requirement, recurrent infection, or recurrent bleeding episodes certainly could be considered triggers to move on to transplantation. Thus it is useful to subdivide patients with lower-risk MDS into more-refined prognostic groups that may benefit from HSCT.

Transfusion frequency and resultant iron overload have both been demonstrated to be important prognostic factors in HSCT outcomes. Platzbecker et al[67] compared the effects of transfusion dependency at the time of HSCT. Even though the transfusion-dependent group had more low-risk features, overall survival was inferior, with a 3-year overall survival of 49% compared with 60% in the transfusion-independent group ($P = 0.1$). The Pavia group examined a cohort of patients stratified by IPSS to determine the relevance of the newer World Health Organization (WHO) histologic classification scheme and to determine if transfusion requirement influenced outcomes among different IPSS groups. For patients with low- and intermediate-1 risk IPSS scores, the WHO histologic classification scheme significantly differentiated survival among the different histologic subtypes within each IPSS range.[68] More importantly, the authors demonstrated a significant effect on survival based on the requirement for transfusion support. As would be expected, outcomes in patients with higher-grade myelodysplasia were affected less by transfusion requirement than were patients with less-advanced WHO histologic classifications. As a result, the impact of transfusion requirement was then incorporated into the WHO Prognostic Scoring System (WPSS).[69] In this system, the effect of regular transfusion requirement (defined as requiring at least one transfusion every 8 weeks in a 4-month period) was given the same regression weight as progressing between cytogenetic risk groups. In contrast to the initial IPSS publication, which carries prognostic information only at the time of initial MDS diagnosis, this model was time dependent, such that patients could be continually reevaluated by the scoring model and updated prognostic information could be generated at any time in the patient's treatment course. As such, the development of new cytogenetic changes or the development of a transfusion need adds useful information that helps guide treatment decisions, including the decision to proceed to HSCT as well as estimating transplantation

outcomes.[70] Determining at which WPSS stage transplantation outcomes are superior to nontransplantation therapy has yet to be determined.

A limitation of both the IPSS and WPSS scoring systems is that they do not account for many important cytogenetic changes. An analysis of cytogenetics in over 2000 individuals with MDS identified several favorable karyotypes that were associated with median survivals that ranged from 32 to 108 months, as well as karyotypes associated with an intermediate prognosis.[71] Some have suggested that adverse cytogenetics be given the same weight as an elevated blast count in the IPSS modeling scheme.[72]

It is worth noting that the majority of the prognostic models discussed here relate largely to patients undergoing high-intensity conditioning HSCT, whereas this procedure is not recommended for the vast majority of patients with MDS because of the age distribution of this patient population. Therefore prognostic models developed specifically for older patients are required. In addition, the optimal timing of RIC transplantation needs to be addressed in a prospective clinical trial, or in the absence of the feasibility of this approach, with mathematical Markov modeling.

Molecular Prognostic Factors

Perhaps even more than in AML, mutation analysis undoubtedly led to a shift from rudimentary clinical prognostic models to molecularly defined models for prognosis and to guide therapy in MDS. As many as 75% of patients can be found to have one or more mutations.[73] Numerous individual genes and whole genome expression profiling have demonstrated significant associations with MDS outcome, although none of these molecular signatures have been tested yet to determine their impact on transplantation outcome. Nonetheless, these gene aberrations are useful in recommending HSCT in the face of an adverse clinical prognosis. The following presents some of the better-characterized lesions and their impact on MDS outcomes.

TET2: TET2 is the most commonly mutated gene in MDS, mutated in over 20% of MDS patients.[74] TET2 is involved in the conversion of 5-methylcytosine to 5-hydroxymethylcytosine and is thus important in the epigenetic modulation by deoxyribonucleic acid (DNA) methyltransferases.[75] Although prevalent, TET2 does not appear to offer prognostic information in MDS.[73,76]

ASXL1: Mutations in ASXL1, a member of the enhancer of trithorax and polycomb (ETP) family, are similar in frequency to mutations of TET2,[77] but they carry prognostic information. Thol et al[78] demonstrated a significantly shorter overall survival with a shortened time to leukemia progression among patients with frameshift mutations in this gene.

IDH1: The citric acid cycle gene IDH1 is mutated in a small proportion of patients with MDS. However, when mutated, it was associated with very poor outcome (14% versus 52% 2-year survival) in a large MDS cohort (n = 153).[79] This finding was not noted in a recent multigene analysis, where, in contrast, the homologue IDH2 had borderline prognostic significance.[73]

DNMT3A: Changes in DNA methylation have been extensively studied in MDS. Point mutations in one of two de novo methylation genes, DNMT3A, have been shown to be present in 8% of MDS patients.[80] These mutations are associated with an adverse prognosis.

EZH2: The protein encoded by EZH2 is a histone methyltransferase that influences stem cell renewal and likely acts as a tumor suppressor in myeloid malignancies.[81,82] In their multigene mutation analysis, Bejar et al[73] noted that mutations in this gene were associated with the highest adjusted hazard for death among 439 patients.

Other mutations: TP53, which is prognostic in many other tumor types appears to be prognostic in MDS.[73] Similarly, the DNA repair gene RUNX1 appears prognostic in MDS.[73] Other genes relevant in AML and other myeloid diseases, such as FLT3, NPM1, and JAK2 appear to have limited utility in prediction of MDS prognosis.[83,84]

In addition to individual gene mutations, the use of whole genome microarray gene expression profiling has been used to estimate prognosis in MDS. Mills et al[85] developed a hierarchic microarray-based risk score on 110 primary MDS samples and were able to stratify the risk for leukemic transformation and predict overall survival using their model.

As the number of patients with a defined molecular signature subtype of MDS that have undergone HSCT increases, the overall benefit (or lack thereof) for early HSCT can eventually be determined. Until then, and in the absence of specific effective therapeutics for each of the molecular adverse-risk subtypes, we can continue to recommend HSCT for patients who carry one or more of these high-risk molecular signatures.

Incorporating Comorbidity for Patient and Conditioning Intensity Selection Before Transplantation

With increased comorbidity comes an increase in the rate of adverse outcomes in hematologic malignancies, and, in particular, in the treatment of MDS.[86] Age alone cannot be used as a surrogate for comorbidity, as demonstrated by an analysis of over 500 individuals with MDS who underwent a first RIC transplantation.[87] Several comorbidity scores have been developed to help provide prognostic information in myeloid malignancies. In MDS, the Hematopoietic Cell Transplantation Comorbidity Index, developed by Sorror and colleagues,[88,89] has been shown to carry prognostic value, even in patients with MDS not undergoing transplantation.[90] The consideration of comorbidity before HSCT is even more relevant now that RIC has been shown to be effective in the treatment of MDS, and patients can elect to undergo RIC transplantation (see Comparative Results: Myeloablative and Reduced-Intensity Regimens in MDS). Patients were divided into four separate groups, with each group being defined on the basis of comorbidity and malignant disease risk. Within each of the four risk groups, patients who underwent MAC and RIC were compared with each other. As expected in each of the four groups, the RIC arm experienced higher relapse rates but lower treatment-related mortality rates when compared to the MAC arm. As a result, disease-free and overall survival was similar between conditioning arms in all four groups.[89]

The effects of elevated ferritin levels on HSCT until recently have been largely limited to patients undergoing MAC transplantation.[91] We previously reported that an elevated pre-HSCT serum ferritin level was strongly associated with lower overall and disease-free survival in patients with AML and MDS after transplantation, and this was largely attributable to increased treatment-related mortality.[91] Similarly, a prospective single-institution study of 190 adult patients undergoing MAC HSCT demonstrated that elevated pretransplantation serum ferritin level was associated with increased risk for 100-day mortality, acute GVHD, and bloodstream infections or death as a composite endpoint.[92] It has now been recognized that elevated ferritin level can predict inferior outcomes even after RIC transplantation.[63] As a laboratory prognostic factor, ferritin should be considered a marker of comorbidity, because ferritin is a marker of inflammation. As such, ferritin levels could influence the decision to pursue high-intensity or reduced-intensity HSCT. Optimally, if high-intensity HSCT is planned, proceeding before the accumulation of a critical amount of iron should be pursued, or, alternatively, chelation therapy before HSCT can be considered, although this latter approach has not yet been demonstrated to be effective in prospective clinical trials.

Pretransplantation Therapy

The role of cytoreductive chemotherapy before HSCT for MDS remains controversial. Many analyses have demonstrated that

outcomes are improved with lower disease burden at the time of HSCT,[93] but previously only conventional chemotherapy was offered. The analyses that compare chemotherapy to no chemotherapy before HSCT are inherently biased, because patients who do poorly or expire with chemotherapy are not included in HSCT outcome data and might have had favorable outcomes if not exposed to cytotoxic agents. On the other hand, responsiveness to chemotherapy may indicate more favorable disease biology and this has been correlated with improved outcomes after HSCT.[94]

With the advent of DNA hypomethylating therapy, the use of conventional chemotherapy has diminished for MDS patients. The effect of DNA hypomethylating therapy on HSCT outcomes has recently been studied by several groups.[95-97] Compared retrospectively, it does not appear that pretransplantation hypomethylating therapy offers a survival advantage,[90] but these agents continue to be used widely to prevent disease progression and to reduce transfusion needs while donor selection is performed in patients destined to undergo transplantation. There may be some advantage to the use of these agents before HSCT, because DNA hypomethylating therapy has been shown to upregulate the expression of cancer-testis antigens,[98,99] killer immunoglobulin-like receptor (KIR) ligands,[100] HLA molecules,[101] and other minor antigens on tumor cells,[102] all of which may enhance graft-versus-MDS effects. Lack of response to DNA hypomethylating therapy is associated with a very poor prognosis [103] and should be an indication for transplantation referral. Finally, hypomethylating agents have been used after transplantation to reduce the risk for relapse,[104] but more studies will need to be undertaken before this type of therapy can be routinely recommended.

FUTURE DIRECTIONS

Despite the progress that has been made in conventional therapy for both AML and MDS, allogeneic HSCT has the best track record for curing the disease. Although HSCT has limitations, reductions in toxicity, improvements in donor availability, and new strategies to enhance GVL while limiting GVHD promise to further improve survival. Advances in mutation analysis provide insights into the pathophysiology of MDS and AML and suggest routes for targeted therapy. However, in many circumstances targeted therapy may not be feasible, and thus the utility of molecular prognostic indicators is to identify patients who will benefit from early transplantation.

CHAPTER 61

ACUTE MYELOID LEUKEMIA IN CHILDREN

Michael C. Wei, Gary V. Dahl, and Howard J. Weinstein

Pediatric acute myeloid leukemias (AMLs) represent a clinically and biologically heterogeneous group of diseases caused by the malignant transformation of a hematopoietic stem cell or myeloid progenitor cell. The proliferative advantage of the leukemic stem cell, coupled with impairments in differentiation and inhibition of apoptosis, is thought to arise from acquired genetic alterations that lead to accumulation of immature or blast cells in the bone marrow. The blasts eventually suppress normal hematopoiesis and infiltrate other organs and tissues. Conventionally, the French-American-British (FAB) cooperative group classified AML into eight subtypes (M0 to M7) based primarily on blast cell morphology and reactivity with histochemical stains. More recently, the World Health Organization (WHO) developed a new classification system that included cytogenetics and lowered the percentage of blasts in the marrow required to make a diagnosis of AML from 30% to 20%. AML accounts for approximately 20% of acute leukemias in children and 80% of those in adults. In contrast to cure rates for childhood acute lymphoblastic leukemia (ALL), cure rates for AML have improved only modestly over the past 2 decades. The use of intensive consolidation chemotherapy with allogeneic stem cell transplants in selective patient groups and better supportive care have resulted in overall survival (OS) rates approaching 70% in some clinical trials. Although some subgroups, such as patients with Down syndrome and acute megakaryoblastic leukemia (AMKL), acute promyelocytic leukemia (APL), and core binding factor leukemias with t(8;21) or inv(16), have excellent outcomes, others continue to have poor outcomes. Much has been learned about the prognostic impact of cytogenetic abnormalities, mutations in specific genes such as FLT3 and CEBPA, and response to therapy as measured by minimal residual disease (MRD). Current cooperative group trials incorporate these factors into risk-adapted therapy such as the recommendation for stem cell transplant for patients at highest risk for relapse. Challenges still remain in how to best identify those patients at risk for relapse and to tailor therapy based on this risk with therapy intensification or novel targeted therapy.

EPIDEMIOLOGY

Approximately 550 new cases of AML are diagnosed each year in children ages 0 to 19 years in the United States. In contrast to the early-age peak (3 to 4 years) for childhood ALL, the incidence of AML is quite constant from birth throughout the first 10 years, with a slight peak in late adolescence. AML also accounts for the majority of the very rare instances of congenital leukemia. The predominance of AML in this age group may in part be due to the inclusion of infants with the transient myeloproliferative disorder associated with Down syndrome (see discussion later in this chapter). There is no difference in incidence between males and females. There is no known relationship between race and the incidence of AML, although Hispanics experience the highest rate of leukemia per million population, from 1.3- to 1.7-fold higher than other racial/ethnic groups.

The incidence and subtypes of acute leukemia in children do not have significant geographic variation. In Japan, China, and among the Maori of New Zealand, however, the rates of AML are the highest. In India and Kuwait, the lowest rates are reported. Patterns of presentation also vary. For example, an unusually high percentage of children diagnosed with AML in Turkey and several African countries present with myeloblastomas or chloromas involving the orbital area. APL accounts for 5% to 8% of pediatric AML cases, and its frequency varies more widely geographically, with increased incidence in Italy and South and Central America. In addition, APL is uncommon in the first decade of life, and its incidence plateaus during early adulthood.

As in other forms of leukemia, the precise cause of AML is unknown. The vast majority of children with AML have no obvious predisposing factors. Known risk factors include several congenital/genetic disorders, ionizing radiation, and certain drug or toxin exposures (Table 61-1). For example, occupational exposure to benzene and treatment with alkylating agents or topoisomerase-II inhibitors (especially the epipodophyllotoxins etoposide or teniposide) are associated with an excess incidence of AML. The likelihood of developing secondary AML from epipodophyllotoxin therapy appears to be schedule- and cumulative dose–dependent. Increased risk has been noted with twice-weekly or weekly administration of etoposide/teniposide. In contrast to alkylating agent–induced AML, which generally causes chromosomal loss of 5q or 7q, the secondary leukemias observed after treatment with etoposide or teniposide are usually myelomonocytic or monocytic in morphology, have a shorter latency period (2 to 4 years), and usually have chromosomal translocations involving band 11q23 (MLL gene rearrangement). The MLL gene is also rearranged in 60% to 70% of cases of infant acute leukemia, and de novo AML, most frequently in AML with myelomonocytic or monocytic morphology. In utero exposure to naturally occurring topoisomerase II inhibitors such as dietary flavonoids has been hypothesized to increase the risk for MLL-rearranged infant AML. Children who were exposed to radiation from the atomic bombs in Japan had an increased incidence of leukemia, but no excess of leukemia was noted in Japanese children who were exposed prenatally to the atomic explosions. Several studies have addressed whether exposure to low-frequency, nonionizing radiation (e.g., electromagnetic fields) is leukemogenic but did not find an increased risk for acute leukemia in children exposed to residential magnetic fields.

Genetic factors predisposing to AML have been studied in twins and in children with certain genetic disorders. Unusual concordance of AML has been observed in monozygotic twins that approaches 100% for infant leukemias and a risk on the order of 1 in 10 for older twin pairs. These leukemias are the consequence of the transplacental passage of a single leukemic clone rather than a genetic predisposition in most cases. Patients with diseases associated with chromosome fragility and impaired deoxyribonucleic acid (DNA) repair mechanisms (e.g., Fanconi anemia and Bloom syndrome) are predisposed to develop AML. Children with congenital disorders of granulopoiesis and erythropoiesis, such as Kostmann syndrome and Diamond-Blackfan anemia, are also at increased risk for developing AML. The cumulative incidence of myelodysplastic syndrome or AML in patients with severe congenital neutropenia receiving long-term granulocyte colony-stimulating factor therapy is 21% after 10 years.

Children with trisomy 21 or Down syndrome have an approximately 10- to 20-fold increased risk for developing acute leukemia compared with children without Down syndrome. Although most

leukemia seen in children is lymphoid, in children with Down syndrome under the age of 4, more than 50% of cases are myeloid, and Down syndrome patients account for approximately 10% of all pediatric AML patients. From birth through 4 years of age, the incidence of AML (especially AMKL) is much greater than ALL in children with Down syndrome. In children with Down syndrome, the incidence of AMKL is up to 500-fold greater than in the general pediatric population. After 5 years of age, the ratio of ALL to AML reverts to that of the general pediatric population.

Children with neurofibromatosis 1 (NF1) are at increased risk for developing acute and chronic myeloid leukemias as well as certain benign and malignant tumors that primarily arise in cells derived from the embryonic neural crest. In patients with NF1 and leukemia, loss of both NF1 alleles in bone marrow blasts has been detected in some patients. These data are consistent with a tumor-suppressor function for the NF1 gene. Inactivation of NF1 may contribute to leukemogenesis by aberrantly activating the RAS signaling pathway.

PATHOBIOLOGY

Chromosomal Rearrangements

Chromosomal abnormalities are detected in blasts from 75% of children with AML and are important for diagnostic and prognostic purposes. The United Kingdom Medical Research Council (UK MRC) published the largest series of childhood AML cytogenetics, which defined 22 subgroups and showed that the distribution of chromosomal changes and the prognostic significance of these changes differed between adult and pediatric patients. Normal karyotype AML accounts for approximately 25% of pediatric patients, compared to 50% in adult AML. Most of the described chromosome changes are not unique to a specific age group, except for the 50% of 11q23 rearrangements seen in infants, the t(l;22)(pl3;ql3) in infants with AMKL, and the t(7;12)(q36;p13) translocation also seen in infants.

Many of the genes at the breakpoints of chromosomal translocations have been cloned and proven to be transcription factors involved in normal hematopoiesis and myeloid differentiation. The translocation t(8;21)(q22;q22) is the most frequently occurring translocation in AML at approximately 14% and is one of the core binding factor leukemias that has a favorable prognosis. Three-way rearrangements may occur. The t(8;21) is frequently associated with loss of a sex chromosome. The t(8;21) produces a fusion protein involving RUNX1/AML1 on chromosome 21 and RUNX1T1/ETO on chromosome 8. The RUNX1 gene encodes one of the DNA-binding α subunits of the heterodimeric core binding factor transcription factor complex. The chimeric fusion protein is thought to function as a transcriptional repressor and recruits corepressors that interfere with normal core binding factor–dependent transcription, thereby inhibiting differentiation and enhancing self-renewal. The RUNX1-RUNX1T1 fusion gene has been detected by molecular methods in patients with t(8;21) in long-term complete remission. In patients with t(8;21) AML, MRD quantitation by real-time reverse-transcriptase polymerase chain reaction (RT-PCR) allows for identification of patients with a higher risk for relapse.

Chromosomal abnormalities involving chromosome 16, inv(16)(p13;q22), or t(16;16)(p13;q22) constitute approximately 7% of AML, represent the second core binding factor leukemia, and are associated with a favorable prognosis and characteristic morphology. The morphology is characteristically myelomonocytic with the distinctive presence of dysplastic eosinophils containing a dense infiltration of large, violet-purple eosinophilic granules. CBFB, encoding the non–DNA binding β- subunit of the core binding factor heterodimer, is disrupted at the 16q22 breakpoint, and MYH11, encoding smooth muscle myosin heavy chain, is disrupted at the 16p13 breakpoint. The resultant fusion product, CBFβ–MYH11, exerts a dominant-negative effect on the core binding factor transcription factor complex, resulting in a block in myeloid differentiation. A high proportion of these leukemias have cooperating mutations thought to lead to increased cell proliferation.

Chromosome band 11q23 translocations are commonly seen in infants and toddlers with the myelomonocytic and monocytic morphology and secondary leukemias after epipodophyllotoxin therapy. Of the 75% of pediatric AML patients with an abnormal karyotype, 11q23 rearrangements were the largest subgroup at 16% of patients. The 11q23 translocation disrupts the MLL gene (mixed-lineage leukemia) that encodes a large protein with regions of homology to the Drosophila trithorax protein. In mammals the wild-type MLL protein functions as a histone methyltransferase involved in maintenance of homeobox (Hox) gene expression and plays a critical role in definitive hematopoiesis. MLL oncogenic rearrangements result in aberrant Hox gene expression and epigenetic chromatin changes. The most common 11q23 translocations observed in childhood AML are t(9;11)(p21;q23), t(11;19)(q23;p13.1), and t(10;11)(p12;q23), although more than 50 MLL translocation partners have been identified. The prognostic significance of the MLL translocation partner is controversial, with some groups reporting a favorable prognosis for t(9;11). MLL translocations are found in both ALL and AML, and the precise reasons for development of one or the other is likely related to the cell of origin and the biology of the specific MLL translocation.

The translocation t(15;17)(q22;q21) is associated with 95% of APL, including both the hypergranular and the hypogranular variants. This has a favorable prognosis because of molecularly targeted differentiation therapy. The cloning of the breakpoint revealed rearrangement of a retinoic acid receptor gene RARA fused to the PML gene. The PML-RARA hybrid gene is expressed in leukemic cells from most patients with APL, though rarely other fusion partners, such as PLZF-RARA t(11;17)(q23;q21) or NPM-RARA t(5;17)(q35;q21), have been reported. The PML-RARA fusion protein is an abnormal retinoic acid receptor with decreased sensitivity to retinoic acid, thereby antagonizing normal differentiation. This molecular marker (PML-RARA transcript) provides a convenient assay for diagnosing APL and determining the presence of MRD. Before the RARA gene was shown to be rearranged in t(15;17), observations were made that APL cells differentiated in response to retinoic acid both in vitro and in vivo. Now it is understood that the mechanism involves driving differentiation by saturating the retinoic acid receptor with pharmacologic levels of retinoic acid.

Cell of Origin and Biologic Properties of Leukemia Stem Cells

Cytogenetic studies and assays using X-linked polymorphisms suggested the clonal nature of AML. The chromosomal changes vary but

predominantly involve balanced translocations, deletions, or inversions and are restricted to the leukemic cells. The bone marrow karyotype returns to normal when the disease is in complete remission. At relapse, often the original clone reappears (plus or minus additional genetic changes), suggesting that the leukemic clone was suppressed, but not eliminated, by treatment. Emerging evidence based on careful analysis of copy number alterations and whole-genome sequencing supports a clonal evolution model of leukemia, in which multiple, genetically distinct leukemic subclones are present at diagnosis. One clone may dominate at diagnosis and reemerge at relapse, or a related but distinct subclone may emerge at relapse.

There is evidence that the cell of origin in AML may be a primitive hematopoietic stem cell (HSC). Studies of human AML leukemic stem cells (LSCs) transplanted into immunodeficient mice indicated that the LSC closely resembles primitive HSC immunophenotypically. However, model systems of human AML using AML oncogenes introduced into phenotypically defined populations of mouse bone marrow cells have demonstrated that both primitive HSC and more differentiated granulocyte-macrophage precursors can be transformed and give rise to AML. Thus more committed progenitors have the potential to be transformed, but whether this occurs in human disease remains uncertain.

Although bulk leukemic blasts have limited capacity for self-renewal, the LSC hypothesis posits that LSCs have the ability to self-renew and generate precursors that give rise to the entire leukemic hierarchy when xenotransplanted into immunodeficient mice. Attempts have been made to define LSC immunophenotypically using cell surface markers such as CD34 and CD38; however, recent studies have shown a remarkable plasticity in the immunophenotype of leukemia-initiating cells. There may be many cells with stem cell–like properties that differ in their genetic profile and ability to initiate leukemia. The frequency of LSCs is thought to be quite rare, but that view is being challenged. Many AML LSCs are found in a quiescent state, which may explain why some patients relapse after treatment with agents that target rapidly dividing cells. Identification of LSCs and targeting therapy to these cells is a major goal of AML research.

Cooperating Mutations

Some oncogenic AML translocations can be generated in utero, indicating a long latency for the development of disease. Given this latency, additional secondary mutations are thought to be required for an initiated cell to progress to overt leukemia. A cooperativity model of leukemogenesis suggests that there are two types of mutations required, one conferring a proliferative or survival advantage and another that impairs hematopoietic differentiation. Although most chromosomal translocations act to impair differentiation, many cooperating mutations affect cellular proliferation. The most frequent known examples in pediatric AML include KIT, RAS, and FMS-like tyrosine kinase-3 (FLT3) mutations. A review of 170 pediatric AML samples showed that 40% harbored a mutation in one of these three genes. Mutations in RAS, a critical mediator of growth signal transduction mutated in many cancers, were found in 37 of 99 pediatric AML samples. Mutated RAS synergizes with nuclear fusion genes to accelerate leukemia latency in mouse models. FLT3 is a receptor tyrosine kinase important for cell proliferation and differentiation. Mutations, including the internal tandem duplication (ITD) or activating loop mutations, are thought to lead to constitutive activation of the receptor. FLT3-ITD expression induces a myeloproliferative disease (but not frank AML) in mice; however, FLT3-ITD increases the penetrance of APL in a PML-RARA model. Somatic FLT3 mutations are found in 10% to 20% of pediatric AML, and most studies have found a lower frequency than that in adult AML.

Analysis of copy number variations (genomic deletions and duplications) using single-nucleotide polymorphism (SNP) arrays indicates, in contrast to ALL, additional copy number variations in AML are rare. Instead, additional mutations are likely to be point mutations or structural changes below the detection level limit of SNP arrays. Many new somatic mutations in AML blasts are being uncovered by whole-genome sequencing. Whole-genome sequencing of adult AML samples revealed mutations in isocitrate dehydrogenase 1 (IDH1) and IDH2 and in DNA methyltransferase 3A (DNMT3A). These mutations were associated with aberrant DNA methylation patterns and found to be prognostically significant. Retrospective studies of pediatric AML samples indicate that these mutations are rare in pediatric AML and not prognostically significant in multivariate regression analysis. These studies highlight some of the molecular genetic differences in pediatric versus adult AML and also potentially reflect a difference in biology (Fig. 61-1). Whether new mutations discovered by sequencing represent driver or passenger mutations will require further study.

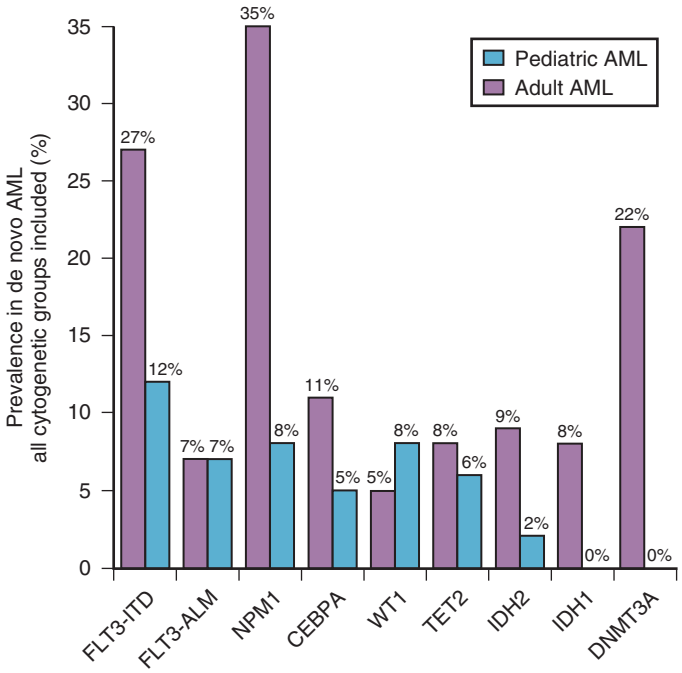

Figure 61-1 PREVALENCE OF GENETIC MUTATIONS IN ADULT VERSUS PEDIATRIC ACUTE MYELOID LEUKEMIA. *AML,* Acute myeloid leukemia. *(Modified from Ho PA, Kutny MA, Alonzo TA, et al: Leukemic mutations in the methylation-associated genes DNMT3A and IDH2 are rare events in pediatric AML: A report from the Children's Oncology Group.* Pediatr Blood Cancer *57:204, 2011.)*

Besides altered proliferation and differentiation properties, AML cells, and particularly AML LSC, may also evade host immune surveillance systems by upregulating the CD47 antigen that functions as a "don't eat me" antiphagocytosis signal for the SIRPα receptor on macrophages. Antibodies that block CD47 make AML cells susceptible to macrophage phagocytosis in animal models and are being developed for human clinical trials.

CLASSIFICATION

Careful examination of both the blood smear and the bone marrow aspirate is required to establish the diagnosis of AML, because approximately 10% of patients with acute leukemia do not have circulating blasts at diagnosis. Various methods are available for characterizing the blast cell population in patients with acute leukemia. These include morphologic interpretation of Wright-Giemsa–stained specimens in conjunction with cytochemistry, chromosome analysis, immunophenotyping, and molecular genetic analysis. Precise diagnosis and classification are essential for successful treatment and biologic investigation of the childhood leukemias.

The FAB group recognizes eight subgroups of AML and also requires a minimum of 30% bone marrow blasts for the diagnosis of AML. The FAB system provides a useful morphologic classification;

however, in many cases there is no correlation between morphology and the underlying genetic abnormality. A new classification for hematopoietic and lymphoid neoplasms was developed by WHO in 1997 and updated in 2008 in conjunction with the Society for Hematopathology and the European Association for Hematopathology. The basic principle of the WHO system is that the classification of hematopoietic neoplasms should identify homogeneous, mutually exclusive entities based on morphologic, genetic, immunophenotypic, biologic, and clinical features to define specific disease entities and provide better correlation with prognosis and underlying biology. The current WHO system classifies AML into several categories: recurrent genetic abnormalities, AML with myelodysplasia-related changes, therapy-related myeloid neoplasms, AML not otherwise specified, myeloid sarcoma, myeloid proliferations related to Down syndrome, and blastic plasmacytoid dendritic cell neoplasm (Table 61-2). In the WHO classification, the blast threshold for the diagnosis of AML is reduced from 30% to 20% in the blood or marrow. In addition, patients with the clonal recurring genetic abnormalities t(8;21)(q22;q22), inv(16)(p13;q22) or t(16;16)(p13;q22), and t(15;17)(p22;q12) are classified as having AML regardless of blast percentage.

New methods for classifying AML include molecular and biologic characterization that may supplant or augment traditional classifications. Gene expression profiling of pediatric AML has identified sets of genes whose expression patterns confer prognostic significance. However, expression-based classifiers have to date not shown any advantage over cytogenetics. Another classification schema based on the pattern of basal and stimulated intracellular phosphoprotein phosphorylation measured by multiplex flow cytometry has described new subsets of AML and has promising prognostic utility. AML can also be classified based on differences in DNA methylation profiles, reflecting altered epigenetics in known AML subtypes and also defining new AML subtypes.

Table 61-2 2008 World Health Organization Classification of Acute Myeloid Leukemia

Acute myeloid leukemia with recurrent genetic abnormalities
Acute myeloid leukemia with t(8;21)(q22;q22); RUNX1-RUNX1T1 (formerly AML1-ETO)
Acute myeloid leukemia with inv(16)(p13.1q22) or t(16;16)(p13.1;q22); CBFB-MYH11
Acute promyelocytic leukemia with t(15;17)(q22;q12); PML-RARA
Acute myeloid leukemia with t(9;11)(p22;q23); MLLT3-MLL
Acute myeloid leukemia with t(6;9)(p23;q34); DEK-NUP214
Acute myeloid leukemia with inv(3)(q21q26.2) or t(3;3(q21;q26.2); RPN1-EVI1
Acute myeloid leukemia (megakaryoblastic) with t(1;22)(p13;q13); RBM15-MKL1
Acute myeloid leukemia with myelodysplasia-related changes
Therapy-related myeloid neoplasms
Acute myeloid leukemia, not otherwise specified
Classify as:
Acute myeloid leukemia, minimally differentiated
Acute myeloid leukemia without maturation
Acute myeloid leukemia with maturation
Acute myelomonocytic leukemia
Acute monoblastic/monocytic leukemia
Acute erythroid leukemia
Pure erythroid leukemia
Erythroleukemia, erythroid/myeloid
Acute megakaryoblastic leukemia
Acute basophilic leukemia
Acute panmyelosis with myelofibrosis
Myeloid sarcoma
Myeloid proliferations related to Down syndrome
Transient abnormal myelopoiesis
Myeloid leukemia associated with Down syndrome
Blastic plasmacytoid dendritic cell neoplasm

Modified from Vardiman JW, Thiele J, Arber DA, et al: The 2008 revision of the World Health Organization (WHO) classification of myeloid neoplasms and acute leukemia: Rationale and important changes, *Blood* 114:937, 2009.

CLINICAL MANIFESTATIONS

The initial signs and symptoms in the majority of children with AML include some degree of pallor, fatigue, skin or mucosal bleeding, or fever or infection that has not responded to appropriate antibiotic therapy. These signs and symptoms reflect the anemia, thrombocytopenia, and neutropenia secondary to diminished production of normal blood cells due to bone marrow infiltration with leukemic blasts. AML, in contrast to chronic myelogenous leukemia, is rarely diagnosed as an incidental finding on a routine complete blood cell count in an asymptomatic child. Bone pain and arthralgias are less common presenting symptoms in children with AML than those with ALL. Massive hepatosplenomegaly is uncommon except in infants with AML. Thrombocytopenia and/or disseminated intravascular coagulation (DIC) is the usual cause of hemorrhage in patients with AML. Bleeding is usually not observed until the platelet count falls below 20,000/μL unless there is an associated coagulopathy. Patients with APL are most at risk for DIC, but infants with myelomonocytic and monocytic AML are also at increased risk. Ocular pathology includes retinal hemorrhages due to coagulopathy, leukostasis, and leukemic infiltration, which may be asymptomatic.

Hyperleukocytosis can cause significant morbidity. Leukostasis refers to plugging of blasts in vessels with invasion of vessel walls, leading to hemorrhagic infarction of the brain, lung, or other organs. Children with AML who have leukocyte counts higher than 100,000/μL are much more susceptible to leukostasis than patients with ALL and comparable white blood cell (WBC) counts, because AML blasts are larger and less deformable. The most clinically relevant target organs for leukostasis are the brain and lung, with signs and symptoms including somnolence, seizures, stroke, tachypnea, and hypoxemia. Symptoms due to hyperleukocytosis require prompt treatment to quickly reduce the leukemic cell burden before the initiation of chemotherapy with leukapheresis, exchange transfusion in the case of infants, and oral hydroxyurea. Although extremely elevated WBC counts and leukostasis are rare in APL, leukapheresis should be avoided in these patients to prevent an exacerbation of DIC.

Congenital Leukemia

The clinical manifestations of leukemia diagnosed in the first 4 weeks of life differ in varying degrees from the typical findings in infants older than 6 months of age and older children with AML. Approximately one-half of newborns and infants younger than 2 months of age with AML have leukemia cutis. These babies have been described as looking like a "blueberry muffin" (Fig. 61-2). The skin lesions are described in the following section. It is important to note that these lesions may precede bone marrow manifestations of leukemia. Transient spontaneous remissions of leukemia cutis may occur but are usually followed within weeks by their reappearance in association with overt bone marrow involvement. In one review of 117 patients with congenital leukemia, there were 6 spontaneous remissions. Spontaneous remission of congenital AML has most often been observed with t(8;16)(p11;p13). Some experts suggest a period of observation only for the infant with leukemia cutis (MLL negative) as well as those with t(8;16), but overall it is recommended that chemotherapy be used for congenital leukemia.

Extramedullary Leukemia

The most common sites of extramedullary leukemia in children with AML include skin, gingiva, and central nervous system (CNS) and myeloblastomas in the head and neck area (Fig. 61-3).

Extramedullary involvement with AML is more common in infants than in older children. The skin lesions of leukemia cutis are often widespread, range in size from several millimeters to several centimeters, and are palpable as freely mobile, generally painless subcutaneous nodules. The color of the overlying skin may be salmon, red-brown, or bluish to slate gray (see box on Extramedullary AML: Myeloid Sarcoma and Leukemia Cutis). Testicular involvement is extraordinarily rare in children with AML and, like CNS leukemia, is commonly associated with the myelomonocytic and monocytic AML.

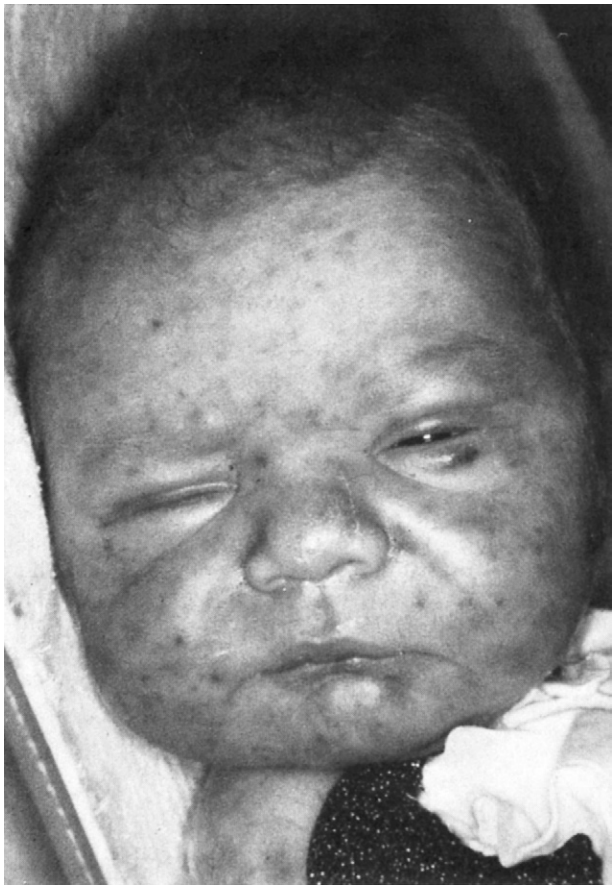

Figure 61-2 LEUKEMIA CUTIS AS COMMONLY SEEN IN CONGENITAL LEUKEMIA.

The most common pathologic finding of AML in the CNS is that of meningeal infiltration by blasts (Fig. 61-4), but epidural or brain parenchymal myeloblastomas have also been described. The incidence of meningeal leukemia at diagnosis in children with AML ranges from 5% to 15%, but most children are asymptomatic. The rare symptomatic patient with CNS leukemia may have headache, vomiting, papilledema, or a cranial nerve palsy (facial nerve is most common). In contrast, patients with cerebral leukostasis present with seizures, somnolence, or stroke secondary to areas of hemorrhage and infarction in brain tissue.

Fewer than 5% of newly diagnosed patients with AML have myeloblastomas, also known as granulocytic sarcomas or chloromas. These "solid tumors" of myeloid blasts may occur anywhere but are

Extramedullary Acute Myeloid Leukemia: Myeloid Sarcoma and Leukemia Cutis

The management of acute myeloid leukemia (AML) presenting with extramedullary disease, including myeloid sarcoma and leukemia cutis, is challenging. Diagnosis of myeloid sarcoma by biopsy is necessary if there are no other indications of leukemia. Diagnosis of leukemia cutis should always be through biopsy and not fine-needle aspiration, and samples need to be prepared for analysis by immunohistochemistry and cytogenetics/fluorescence in situ hybridization (FISH). Treatment should be with systemic chemotherapy based on risk stratification of the underlying disease cytogenetics and mutational profile. Radiation therapy as consolidation should be considered, especially if there is an incomplete response with chemotherapy alone and with careful evaluation of site and potential toxicities. Imaging of myeloid sarcoma sites by computed tomography (CT), positron emission tomography (PET), or magnetic resonance imaging (MRI) can be used to monitor response to treatment. There may be prognostic significance of extramedullary disease occurring at certain sites such as the orbit, but this should not influence choice of systemic therapy. The presence of leukemia cutis is a marker of aggressive disease. Isolated myeloid sarcoma or leukemia cutis relapse should be treated as a systemic relapse, because progression to systemic relapse is almost universal. Leukemia cutis as relapse after transplant is particularly difficult to treat. Total skin electron beam irradiation can be used and often achieves a transient response with cessation of new lesions and regression of old lesions, but recurrence or progression is typical. Caution must be used with concurrent chemotherapy that may induce a radiation recall reaction.

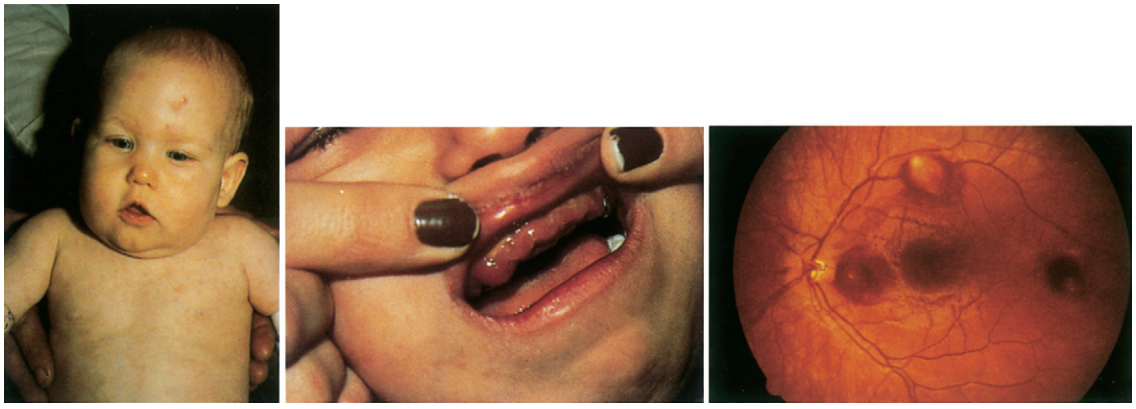

Figure 61-3 A, Monoblastic leukemia cutis at diagnosis; lesion on forehead preceded disseminated rash by 6 to 8 weeks. **B,** Gingival infiltration with M5a leukemia in a 21-month-old girl. **C,** Retinal infiltration at presentation of M4 disease in a 5-year-old boy.

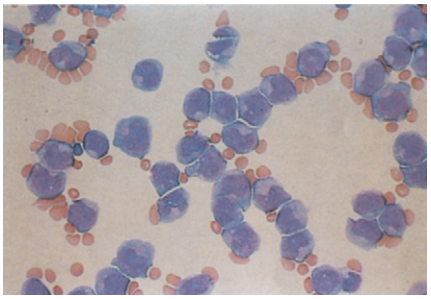

Figure 61-4 CEREBROSPINAL FLUID DOUBLE-CONCENTRATE CYTOCENTRIFUGE PREPARATION OF MONOCYTIC ACUTE MYELOID LEUKEMIA CELLS.

primarily detected in the bones and soft tissues of the head and neck (often orbits), and in intracranial or epidural locations. Myeloblastomas may herald overt bone marrow involvement with AML by weeks to months and are associated with t(8;21) and, in infants, with myelomonocytic and monocytic AML.

LABORATORY MANIFESTATIONS

The initial WBC count at presentation in children with AML is variable (1000/μL to 500,000/μL). Approximately 15% to 20% of children have WBC counts higher than 100,000/μL. Marked leukocytosis is associated with myelomonocytic and monocytic subtypes and congenital leukemia, whereas lower leukocyte counts are commonly seen in patients with APL. The leukocyte differential in most patients includes fewer than 1000 neutrophils per microliter and a variable percentage of blasts. In approximately 10% of patients, no peripheral blasts are detectable. Most patients with AML have a normocytic anemia, with occasional teardrop forms and nucleated red blood cells noted on the peripheral smear. The rare hemolytic anemia associated with AML is usually microangiopathic, secondary to DIC. Approximately 50% of children with AML present with platelet counts of fewer than 50,000/μL.

The definitive diagnosis of acute leukemia is made by examination of the bone marrow aspirate. In most patients, the bone marrow is hypercellular, with 20% to 90% blasts. The bone marrow biopsy may be hypocellular, especially in patients with a history of prior myelodysplastic syndrome (MDS), Fanconi anemia, or paroxysmal nocturnal hemoglobinuria. Dysplastic changes have recently been reported in patients with de novo AML and appear to have no prognostic significance. Conventional cytogenetic analysis of chromosome banding is usually sufficient to detect recurrent chromosomal rearrangements. Fluorescence in situ hybridization tests for specific chromosomal rearrangements and is often used for t(8;21) and 11q23 rearrangements (MLL break-apart probes); it can detect subtle abnormalities that are not evident in banding studies.

Immunophenotypic Analysis

Normal hematopoietic cells undergo changes in expression of cell surface markers as they mature from stem cells into cells of a committed lineage. Monoclonal antibodies have been developed that react with lineage-specific and stage-specific lymphoid and myeloid activation and differentiation antigens. By using a combination of monoclonal antibodies recognizing B-cell, T-cell, and myeloid antigens and flow cytometry, it is possible to confirm the diagnosis of AML and to differentiate AML from ALL if morphologic findings are inconclusive (<15% of cases).

Approximately 10% to 25% of AML patients demonstrate lymphoid antigen expression on myeloid blasts, and similarly 4% to 25% of ALL patients demonstrate expression of at least one myeloid antigen on the blast cell surface. The expression of lymphoid antigens in AML lacks prognostic significance. In most instances of hybrid or mixed-lineage acute leukemia, there is coexpression of lymphoid and myeloid markers on the same blast, but in rare cases there have been two distinct populations of blasts. The pathogenesis of these mixed-lineage leukemias remains poorly understood. They may represent a leukemic transformation in a primitive stem cell, or the aberrant expression of a lymphoid gene in a myeloid leukemia. Because few instances of true biphenotypic leukemia have been described, the prognosis is unclear. In a pediatric study, 14 of 16 patients with lymphoid antigen–positive AML expressed a T-cell marker. Interestingly, several of these patients had a poor response to AML induction therapy but subsequently responded to an ALL induction regimen. Despite this, children with AML whose blasts express lymphoid antigens should be treated initially on AML protocols.

Table 61-3 Risk Group Stratification in Children's Oncology Group Acute Myeloid Leukemia Trial COG AAML0531

Low risk: core binding factor leukemia (inv[16]/t[16:16], t[8;21])
High risk: -7, -5, 5q-, FLT3-ITD high allelic ratio, >15% blasts at end of course 1
Intermediate risk: absence of low-risk or high-risk features

FLT3-ITD, FLT3 internal tandem duplication.

DIFFERENTIAL DIAGNOSIS

The diagnosis of AML is usually straightforward after an examination of the peripheral blood and bone marrow. Other diagnoses that can sometimes cause diagnostic difficulty include the myeloproliferative disorders (e.g., juvenile myelomonocytic leukemia), myelodysplastic (preleukemic) syndromes, and overwhelming bacterial infections that result in leukemoid reactions or neutropenia secondary to a bone marrow maturation arrest in granulocytic precursors. In the last situation, the bone marrow may be confused with APL, but with resolution of the infection, granulocytic maturation ensues. The differential diagnosis of congenital leukemia is somewhat more challenging, in part because of the leukoerythroblastic peripheral blood picture noted in neonates with hypoxia or sepsis. Congenital viral infections, including cytomegalovirus, herpes simplex, human immunodeficiency virus (HIV), and rubella, need to be ruled out as well as the transient myeloproliferative disorder associated with trisomy 21.

PROGNOSIS

Prognostic factors in AML depend on disease characteristics such as cytogenetics, FAB subtype, and associated mutations; host factors; and response to therapy. Favorable-risk patients with APL or Down syndrome patients with acute megakaryoblastic leukemia are treated with separate therapeutic regimens. Although many factors are prognostic, most current pediatric protocols use cytogenetics, additional genetic mutations such as FLT3-ITD, and response to therapy to divide patients into favorable, intermediate, and unfavorable risk groups that are assigned to risk-adapted regimens. There is no standard risk stratification among all of the worldwide cooperative groups. The current Children's Oncology Group (COG) risk stratification is summarized in Table 61-3 and will likely change in the future as new factors identifying better- and poor-risk features are identified.

Disease-Associated Risk Factors

Cytogenetics

Favorable-risk cytogenetics include the core binding factor leukemias with inv(16) or t(8;21) and APL with t(15;17). The St. Jude AML02 study reported 3-year event-free survival (EFS) greater than 84% and 3-year OS greater than 90% for both core binding factor leukemia

groups. The Italian Pediatric Hematology and Oncology Group AIDA 0493 trial for APL reported a complete remission (CR) rate of 96%, 10-year EFS of 76%, and 10-year OS of 89%. Poor-risk cytogenetics include monosomy 7 and del(5q). UK MRC AML 10 and 12 trials reported 10-year OS of 32% and 27%, respectively. A novel finding from this study was the poor outcome with abnormalities of 12p with an OS of 35%. Monosomy 5, an adverse cytogenetic marker in adult AML, was not reported in this pediatric series. Abnormalities of 3q, an adverse prognostic factor in adults, had an OS of 57%. Complex karyotype (more than three independent abnormalities) was not an independent prognostic abnormality when adjusted for the presence of other prognostic cytogenetic changes. The 10-year EFS for t(6;9) was 10% with small numbers of patients. Intermediate-risk patients include all others not designated favorable or high risk. Of note, patients with 11q23/MLL rearrangements demonstrated no difference in outcome when compared to patients without MLL rearrangements, with a 10-year OS of 61% in the MRC data.

Non–Down Syndrome Acute Megakaryoblastic Leukemia

Whereas Down syndrome patients less than 4 years of age with AMKL have a favorable prognosis with reduced-intensity chemotherapy, non–Down syndrome patients have a poor prognosis with OS 14% in one single-institution review of 29 patients. Survival was higher in patients who underwent allogeneic stem cell transplant rather than chemotherapy alone. Predominantly seen in infants with non–Down syndrome AMKL, t(1;22)(p13;q13) accounts for one-third of patients with non–Down syndrome AMKL. The WHO recognizes t(1;22) as a distinct biologic entity, and the expression of the fusion gene RBM15-MKL1 can induce AMKL in mouse models. Patients with AMKL and t(1;22) have a better prognosis; in a series of 11 patients the 3-year EFS was 50%, and these patients may not need transplant compared to other patients with non–Down syndrome AMKL without t(1;22).

Leukocyte Count

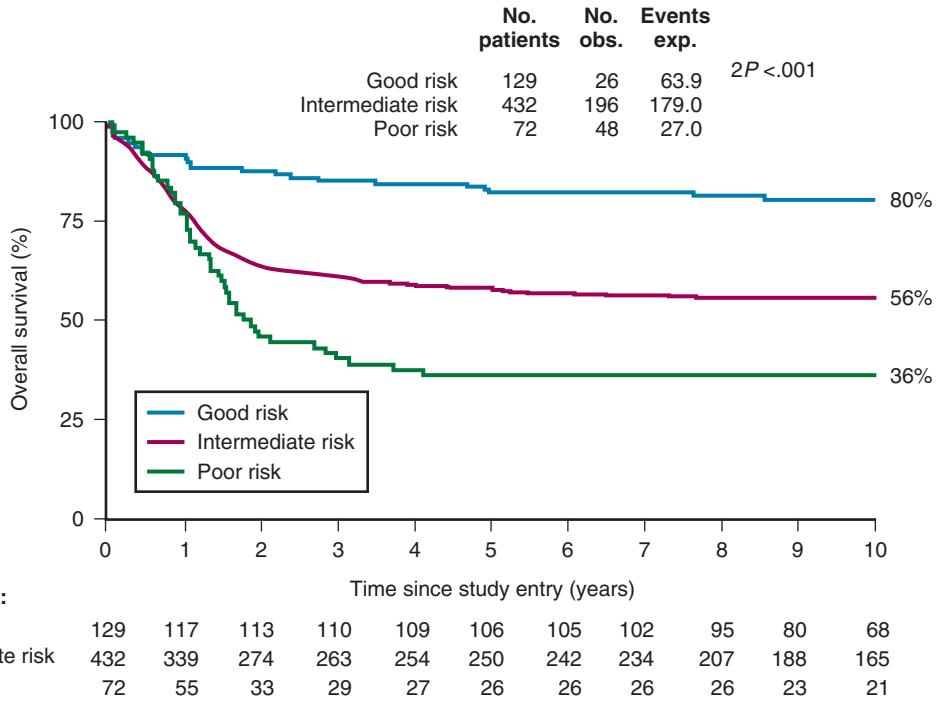
A WBC count greater than 100,000/μL has been considered a poor prognostic factor. In the St. Jude AML02 trial, however, patients with WBC above or below 50,000/μL had similar outcomes. WBC count is prognostic in APL, and children with WBC greater than 10,000/μL have a higher risk for relapse. The presence of acute mixed-lineage or biphenotypic leukemia (AML with lymphoid-associated antigens) does not influence prognosis.

Genetic Mutations

Additional mutations or aberrant gene expression beyond the characteristic chromosomal translocations are found in AML blasts that have biologic and prognostic significance. As discussed earlier, patients with a somatic FLT3-ITD produce an abnormal protein that confers constitutive activation. FLT3-ITD mutations are found in approximately 12% of pediatric AML and have a poor prognosis regardless of subtype of usually less than 30%. FLT3 activating loop mutations do not appear to be prognostically significant. Because a proportion of patients with FLT3-ITD do well, the role of the wild-type allele has been studied, and the ratio of mutant FLT3-ITD allele to wild-type FLT-3 allele PCR products has been found to be prognostic in retrospective analyses. A mutant to wild-type allelic ratio of greater than 0.4 is being studied prospectively by the COG. The St. Jude collaborative group places patients with FLT3 mutation into a poor-risk category and is evaluating this risk stratification prospectively.

CEBPA encodes the CCAAT/enhancer binding protein-α protein that functions as a basic leucine zipper domain transcription factor that regulates proliferation and granulocytic differentiation. Mutations in CEBPA that cause a premature stop or disrupt the DNA-binding domain were found in adult patients with minimally differentiated AML, AML without maturation, and normal karyotype AML, and these mutations conferred a favorable prognosis. CEBPA mutations were found in 4.5% of a series of 847 pediatric patients and found to be an independent favorable prognostic factor.

The Wilms tumor suppressor gene WT1 is a zinc-finger protein transcription factor. WT1 mutations occur in the zinc-finger DNA-binding domain and are predicted to disrupt DNA binding, but the prognostic significance of WT1 mutations or overexpression has been controversial. Nucleophosmin (NPM1) is a nucleocytoplasmic shuttling protein that regulates the P53-ARF tumor suppressor pathway. Mutations in NPM1 have been found that alter its intracellular localization, and mutated NPM1 is associated with better response to induction and survival in adults. There have been conflicting reports on the prognostic significance of NPM1 mutations in pediatric AML. KIT receptor tyrosine kinase mutations were found in adult core binding factor AML and also pediatric AML but were not found to be prognostically significant. NRAS mutations had no clinical prognostic implication. There have been studies of gene expression levels (WT1, VLA-4, VEGFC, BRE) that divide patients into groups based on whether gene expression is above or below the median and then compare the outcome of the groups. Such studies are difficult to adapt moving forward given the continuous nature of the gene expression variable.



Host Factors

Host factors that influence prognosis include age, race, and body mass index (BMI). Age at diagnosis less than 2 years or greater than 10 years has been found to influence outcome in some studies. In AML02, age greater than 10 years was an adverse prognostic factor, but the recent COG AAML03P1 study of 305 patients did not show an adverse impact of age. Some racial disparities in outcome have been studied, with a trend toward inferior outcome in African American patients compared to white patients. Patients who are underweight (<10%) or overweight (>90%) based on BMI have had worse OS and increased treatment-related mortality.

Response to Treatment

Response to treatment is assessed by morphology and MRD. UK MRC AML 10 reported that primary induction failure with greater than 15% blasts after one course of induction was associated with an extremely poor outcome with survival of 22%. Patients with 5% to 15% blasts had similar survival as patients with complete remission with less than 5% blasts by morphology.

MRD analysis detects leukemic blasts at much higher sensitivity than traditional bone marrow morphologic analysis. MRD can be measured with flow immunophenotyping or PCR for specific translocations or genes associated with disease. Assays with RT-PCR for many of the common gene rearrangements in AML are now available for diagnostic purposes and for following minimal residual leukemia. Genetic markers suitable for RT-PCR studies are found in almost 50% of AML patients. One disadvantage is that leukemic cells may vary in the amount of transcript per cell for an individual chromosomal rearrangement or between patients, making precise quantitation challenging. Flow immunophenotyping can detect an aberrant leukemic phenotype in more than 85% of AML patients at 0.1% to 0.01% residual cells, and detection of more than 0.1% MRD after one round of induction or at end of consolidation was associated with a significantly worse risk for early relapse and OS. Importantly, immunophenotyping detected residual leukemia in 27% to 34% of cases in morphologic remission. In the St. Jude AML02 trial, MRD greater than 1% after induction 1 was an independent prognostic factor for survival. This effect was most pronounced in high-risk patients; MRD was not a significant predictor of relapse or induction

No. at risk:

Good risk: t(8;21) and inv(16); poor risk: abn(12p), t(6;9), abn(5q), monosomy 7, t(9;22); intermediate risk: patients not included in the other two groups. *(From Harrison CJ, Hills RK, Moorman AV, et al: Cytogenetics of childhood acute myeloid leukemia: United Kingdom Medical Research Council treatment trials AML 10 and 12.* J Clin Oncol *28:2674, 2010.)*

failure among patients with low-risk or standard-risk disease. CCG-2961 studied MRD levels greater than 0.5% and found 13% of patients with responsive disease (<30% blasts) had occult leukemia, and the presence of occult leukemia was an independent risk factor for OS. Dutch Childhood Oncology Group and MRC results indicate that MRD after induction 1 is a significant independent prognostic factor. The Berlin-Frankfurt Muenster (BFM) group, however, has suggested that MRD is not more predictive of relapse than other traditional prognostic factors such as cytogenetics. Remission by MRD instead of morphology and whether MRD-positive patients benefit from intensified therapy is being studied.

Overall, the use of cytogenetics, MRD, and specific gene markers to predict patients with higher risk for relapse must be further studied prospectively. Current classification schemes predict prognosis for three broad risk categories (Fig. 61-5). There are differences in the prognostic utility of specific gene mutations in adult and pediatric AML. Eventually prospective studies may be used to stratify specific intermediate- or high-risk patients for more intensive or targeted therapy or hematopoietic stem cell transplantation (HSCT). Cooperative groups differ significantly in risk-assignment strategies (see Table 61-3). These classification schema still do not accurately predict specific patients who will ultimately relapse, and newer markers such as phospho-flow must be measured against these established prognostic factors.

THERAPY

The long-term survival (>5 years) rate for children with AML has increased from less than 10% to approximately 60% to 70% during the past 30 years (Table 61-4). This improved cure rate has resulted from more effective remission induction chemotherapy and better strategies to prevent relapse. Current regimens for treating pediatric AML consist of aggressive induction therapy based on a combination of cytarabine and anthracycline to achieve complete remission, followed by consolidation with high-dose cytarabine-based blocks of chemotherapy or stem cell transplant. The decision on transplant depends on risk for relapse, availability of a matched sibling or unrelated donor, and risk for transplant-related mortality. Unlike ALL, there is no extended maintenance therapy, except for APL. Intrathecal CNS treatment and prophylaxis is important, and most groups do not use CNS irradiation. Improvements in supportive care have also been important, making it safe and feasible to treat patients with myelosuppressive doses of chemotherapy. All children with AML should be referred to a pediatric oncology center for treatment and are usually enrolled on a cooperative group clinical trial.

Supportive Care

Excellent supportive care to facilitate children's surviving therapy without significant morbidity is of paramount importance. Before chemotherapy is started, the infant or child should be stabilized with regard to renal, metabolic, hematologic (anemia, bleeding, DIC, leukostasis), and infectious disease issues. A double-lumen indwelling central venous catheter should be placed early in the treatment course. The metabolic derangements associated with leukemic cell death (tumor lysis syndrome) include hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. The tumor lysis syndrome is seen more often in children with ALL (especially T cell and mature B cell) than in those with AML. Uric acid nephropathy is avoided by prompt attention to hydration, alkalinization of the urine, and administration of allopurinol. Alternatively, recombinant urate oxidase (rasburicase) converts uric acid to more soluble allantoin and is now used with outstanding efficacy in children expected to have tumor lysis syndrome.

Children with AML are at especially increased risk for bacterial and fungal infections during therapy- and leukemia-induced neutropenia. The most commonly encountered fungal infections are due to *Candida* and *Aspergillus* species. Given the high risk for fungal disease, it is reasonable to provide antifungal prophylaxis during AML therapy; however, there is no standard antifungal prophylactic

Table 61-4 Outcomes From Recent Cooperative Group Pediatric Acute Myeloid Leukemia Trials

	Years of Study	No. of Patients	Early Deaths (%)	Complete Remission Rate (%)	3- or 5-yr EFS	SE	3- or 5-yr OS	SE	First Author

regimen. Fluconazole is effective against most *Candida* species but has no activity against *Aspergillus* species. Current commercially available agents with anti-*Aspergillus* activity that have been used in AML patients include the triazoles (itraconazole, voriconazole, and posaconazole), the echinocandins (caspofungin, micafungin, and anidulafungin), and amphotericin B deoxycholate or the lipid preparations of amphotericin. In patients with AML, septicemia due to α-hemolytic streptococcal organisms is associated with high-dose cytarabine, a component of most AML therapeutic protocols. The α-hemolytic streptococcal infections have a high rate of recurrence and associated toxicities during subsequent episodes of intensive chemotherapy. Physicians caring for these children must maintain a high index of suspicion and be prepared to institute appropriate antibiotic coverage in the event of fever or unexplained illness. Administration of prophylactic antibiotics (cefepime, vancomycin, ciprofloxacin) during periods of neutropenia are being studied to prevent septicemia. Prolonged periods of neutropenia have been treated with hematopoietic growth factors (granulocyte or granulocyte-macrophage colony-stimulating factor) during induction and after cycles of intensification chemotherapy, although not all protocols use them. Blood products should all be leuko-poor and irradiated to prevent transfusion-associated graft-versus-host disease. Platelet transfusions are recommended prophylactically if the platelet count is lower than 10,000/μL. The most disturbing gastrointestinal toxicity during therapy is an enterocolitis involving the distal ileum, cecum, and proximal colon. This syndrome is referred to as typhlitis or the right lower quadrant syndrome and is noted in approximately 10% of patients. The signs and symptoms of typhlitis develop approximately 10 to 14 days after the start of chemotherapy. Treatment recommendations include bowel rest and double-coverage broad-spectrum antibiotics for gram-negative organisms. Surgery is rarely needed and is reserved for intestinal perforation, abdominal wall fasciitis, or massive bleeding.

One percent to 2% of children with AML still die within the first several days to a week after diagnosis. These early deaths usually result from intracranial hemorrhage from either a coagulopathy or CNS leukostasis. If the leukocyte count is greater than 100,000/μL, it is important to initiate urgent measures to prevent leukostasis with leukapheresis, exchange transfusion, or hydroxyurea.

Remission Induction

Because of the narrow therapeutic index of the active agents in AML, all induction regimens (except for APL) are designed to produce rapid bone marrow hypoplasia, an apparent prerequisite for successful remission induction. The combination of cytarabine (7 days) and daunorubicin (3 days), known as the "7+3" regimen, has been the traditional backbone of induction chemotherapy. Approximately one-third of these patients require two courses of induction to achieve a remission. Protocols using intensified induction by timing or dose intensity (10 to 12 days of cytarabine or high-dose cytarabine) have demonstrated improved remission rates between 83% and 94% with superior OS (see Table 61-4). Children's Cancer Group CCG-2891 compared standard timing, allowing for hematologic recovery, with intensive timing during induction and found that remission rates were similar but EFS was improved with intensive timing. The addition of a third agent such as etoposide or thioguanine during induction is now widely used, and a randomization of DAT (daunorubicin, cytarabine [ara-C], thioguanine) versus ADE (cytarabine [ara-C], daunorubicin, etoposide) in MRC AML 10 showed no significant differences between the two induction regimens. Patients receiving intensified induction have had statistically significant increases in disease-free survival compared with those patients randomized to standard 7+3 induction. These data are consistent with the hypothesis that more effective early leukemic cell kill reduces the likelihood of a subsequent relapse in children and adults with AML. Lower remission rates are seen in patients with therapy-related AML, a history of a prior MDS, and certain cytogenetic findings or gene mutations (see Prognosis). Because of the requisite period of bone marrow hypoplasia and the greater impairment of bone marrow reserve in patients with AML, the remission induction phase of therapy is more toxic than for patients with ALL. A major concern is the appropriateness of current dose adjustments made in chemotherapy protocols for infants less than 1 year of age (generally based on milligram-per-kilogram arbitrary dose reductions of 25%). Prospectively controlled pediatric and adult cooperative group studies have shown that daunorubicin is preferable to doxorubicin because it is associated with less oral mucositis and gastrointestinal toxicity. Several adult and pediatric AML studies have explored the benefits of substituting either mitoxantrone or idarubicin for daunorubicin. Mitoxantrone is at least as effective as daunorubicin. Idarubicin is not superior to daunorubicin for remission induction and is associated with more marrow toxicity and greater number of days until neutrophil recovery. Gemtuzumab ozogamicin is a humanized monoclonal antibody against CD33 conjugated to the calicheamicin toxin. This antigen-directed therapy has been combined safely with standard induction and consolidation regimens. Hepatotoxicity, including venoocclusive disease, has been reported. Gemtuzumab ozogamicin was recently withdrawn from the United States due to lack of clear-cut benefit in improving overall outcome.

Acute Promyelocytic Leukemia

In the past, approximately 65% to 75% of patients with APL entered remission after a standard induction with daunorubicin and cytarabine. The remission induction period, however, was associated with significant early mortality secondary to hemorrhagic complications. Prompt all-trans retinoic acid (ATRA) therapy, without waiting for confirmation of molecular diagnosis, has reduced, but not eliminated, these hemorrhagic complications. ATRA appears to downregulate tissue factor expression and thereby reduces the severity and duration of DIC in APL patients. At present, all patients should be carefully

followed with serial coagulation studies (partial thromboplastin time, prothrombin time, fibrinogen, and fibrin split products). The optimal management of coagulopathy is controversial.

European and American clinical trials have established the current standard front-line therapy, which combines ATRA with anthracycline-based chemotherapy for remission induction and consolidation chemotherapy and with ATRA continuing during 2 years of maintenance, resulting in complete remission rate greater than 90% and OS higher than 80%. The ATRA-induced remissions are associated with differentiation of the blasts/promyelocytes into mature granulocytes. Recent results support a potential role for the addition of cytarabine for patients at higher risk for relapse with initial WBC count greater than 10,000/μL. Unlike other AML subtypes, APL patients benefit from a maintenance course of ATRA-containing therapy for a duration of 2 years.

Arsenic trioxide (As_2O_3 or ATO) has impressive activity in relapse and de novo APL. ATO binds the PML moiety of the PML-RARA oncoprotein, leading to the recruitment of the small ubiquitin-like protein modifier (SUMO)-conjugating enzyme UBC9 and subsequent degradation of PML-RARA. The potential benefit of arsenic in consolidation remains controversial despite the results of the U.S. Intergroup study showing a significant benefit in EFS and OS for patients receiving two courses of arsenic given immediately after CR. The rare (1% of APL) variant PLZF-RARA t(11;17)(q23;q21) is insensitive to ATRA or ATO; other rare alternative rearrangements seen in APL may be treatable with ATRA.

ATRA is associated with several life-threatening complications, including severe respiratory distress and capillary leak syndrome and pseudotumor cerebri (more common in pediatric patients). The retinoic acid syndrome (respiratory distress and weight gain) has been successfully managed in most patients by temporary cessation of ATRA and administration of dexamethasone. The symptoms of pseudotumor cerebri disappear within days after withdrawal of ATRA, and the drug can usually be safely restarted at a reduced dose. This syndrome has also been seen in response to treatment with ATO and thus might better be termed the *differentiation syndrome.*

The ability to detect PML-RARA messenger RNA by RT-PCR is a useful method of monitoring the efficacy of therapy. When used at the 10^{-4} sensitivity level, persistent positive RT-PCR findings after the consolidation phase strongly predict hematologic relapse. Those patients in molecular relapse can be reinduced and treated with stem cell transplant. ATO can be used to achieve remissions in those patients who relapse after ATRA treatment.

Central Nervous System Leukemia

All pediatric AML studies include intrathecal chemotherapy, because isolated CNS relapse occurs in approximately 20% of children with AML who did not receive any CNS-directed therapy, and CNS relapse is associated with worse survival. Cytarabine alone or triple intrathecal therapy with cytarabine, methotrexate, and hydrocortisone are the most commonly used regimens worldwide. In contrast to ALL, the finding of blasts in the CSF at diagnosis in children with AML does not adversely affect prognosis. An accepted approach for the treatment of CNS leukemia is weekly intrathecal chemotherapy until the CSF is clear of blasts. In some protocols, this is followed by CNS irradiation at the end of systemic chemotherapy.

Treatment in Remission

Without further treatment after standard induction chemotherapy, more than 90% of patients relapse within 1 year, and the remainder relapse by 2 years. The intensity and duration of chemotherapy in remission, as well as the role of HSCT in first remission, have been areas of active investigation and controversy during the past decades. In the 1970s, pediatric AML studies tested whether modestly myelosuppressive combination chemotherapy given in remission would improve OS. These protocols led to a plateau in disease-free survival of 15% to 20% at 5 years. In an effort to improve upon these disappointing results, other approaches were explored, including early intensification or consolidation chemotherapy and HSCT. Allogeneic HSCT provided an opportunity for delivering very high doses of chemotherapy and/or irradiation and possibly stimulating a graft-versus-leukemia effect. Although the initial studies were not randomized, the results suggested a benefit for either the intensification of chemotherapy or HSCT early in first remission. Cytarabine, the single most active agent in AML, was the prototype drug for intensification, because laboratory and clinical studies indicated that a log increase in its dose could overcome certain mechanisms of resistance. Approximately 40% of patients with AML who are refractory to standard doses of cytarabine achieve a complete remission with high-dose cytarabine. The superiority of high-dose compared to standard-dose cytarabine has also been confirmed in a prospective randomized clinical trial in adults with AML. Most pediatric AML studies that were initiated in the 1980s and 1990s included several consolidation cycles of high-dose cytarabine. These protocols resulted in 5-year leukemia-free survival plateaus of 35% to 60%. Clinical studies in the most recent decade have evolved and indicate that timed sequential induction and therapies using repeated courses of intensive consolidation result in 5-year EFS rate of 50% to 60%. High-dose cytarabine is given alone or in combination with other agents such as mitoxantrone, asparaginase, or etoposide. The optimal number of consolidation chemotherapy cycles has not been determined but is usually two to three cycles. Maintenance chemotherapy with oral thioguanine and standard doses of cytarabine given after consolidation chemotherapy has not been shown to further increase the proportion of patients in long-term remission. Patients who receive maintenance have a poor salvage rate if relapsed because of clinical drug resistance.

Haploidentical natural killer cell transplant is a novel regimen to maintain remission after consolidation. In the St. Jude NKAML pilot study, 10 favorable- or standard-risk patients in remission received an immunosuppressive regimen followed by KIR-mismatched natural killer (NK) cell infusion. The 2-year EFS was 100% with minimal toxicity, and this approach is being studied further.

Hematopoietic Stem Cell Transplantation in First Remission

Allogeneic HSCT from a histocompatible family donor was first evaluated in children and young adults with AML in first remission in the mid-1970s. Published data from many pediatric AML bone marrow transplant series show 5-year EFS rates ranging from 56% to 74%. Many of the early transplant studies, however, were not prospectively designed and therefore were biased in their selection criteria, were not controlled for the timing of HSCT in first remission, and excluded patients who were eligible for a transplant but who relapsed before the procedure. In an effort to avoid these and other biases, it was suggested that the outcomes of studies comparing HSCT to chemotherapy be analyzed according to the intention-to-treat analysis, which includes all eligible patients (i.e., those having a matched family donor) and not just individuals who actually received the transplant. When the data are analyzed in this way, there is still a statistically significant OS advantage for allogeneic HSCT compared with chemotherapy in some studies. In the setting where no matched related donor was available, three randomized trials concluded that autologous stem cell transplant was not beneficial compared to intensive chemotherapy for consolidation (see box on Role of Hematopoietic Stem Cell Transplantation in Pediatric Acute Myeloid Leukemia).

Allogeneic HSCT early in first remission using an HLA-matched related donor results in a significantly better disease-free survival rate as compared with chemotherapy but is limited to approximately 20% of patients with a suitable donor. There is significant risk for acute (acute graft-versus-host disease, interstitial pneumonia, hepatic veno-occlusive disease) and chronic morbidity (growth problems, gonadal toxicity, secondary malignancy, and chronic graft-versus-host disease)

Role of Hematopoietic Stem Cell Transplantation in Pediatric Acute Myeloid Leukemia

Outcomes in pediatric acute myeloid leukemia (AML) show a benefit for allogeneic transplant in first remission for select patients, but the risk for treatment-related mortality with transplant must be weighed against the improved outcomes with chemotherapy alone because of sequential dose-intensive regimens. The choice of chemotherapy versus hematopoietic stem cell transplantation (HSCT) in first remission therefore depends on prognostic factors and the availability of a suitable donor. The authors recommend matched related or, if a sibling donor is unavailable, matched unrelated HSCT for patients with high-risk features, including monosomy 7, FLT3 internal tandem duplication mutation, and patients with refractory disease after two courses of induction. Allogeneic HSCT in first remission should also be considered for non–Down syndrome patients with French-American-British (FAB) M7 morphology given recent reports of poor outcomes with this subtype. Favorable-risk patients (i.e., Down syndrome M7, inv[16], t[15;17], t[8;21]) should be treated with chemotherapy alone. All other patients without high-risk features in first remission should be treated with consolidative chemotherapy alone, because multiple studies have shown equivalent outcomes compared to autologous or allogeneic transplant. For these patients without high-risk features, matched related or matched unrelated HSCT should be reserved for relapsed disease. An autologous transplant should be considered in second remission when there is no suitable allogeneic donor. Haploidentical transplants are still considered experimental but show promise as an alternative especially with a KIR mismatch.

FLT3

Patients with FLT3 internal tandem duplication (FLT3-ITD) mutation are at a higher risk for relapse, with estimates of overall survival at approximately 30%. The optimal management of these patients is still controversial, and there are several approaches by different cooperative groups. The Children's Oncology Group has identified subsets of patients who are at higher risk, based on the ratio of polymerase chain reaction amplification of wild-type versus FLT3-ITD alleles. The St. Jude collaborative group places patients with FLT3-ITD and minimal residual disease of 0.1% or more in the high-risk category. The United Kingdom Medical Research Council does not assign risk category based on FLT3-ITD status, but patients with FLT3-ITD are randomized to receive lestaurtinib. Kinase inhibitors such as lestaurtinib, sorafenib, and newer agents are being studied in combination with standard acute myeloid leukemia therapy, but their efficacy has not been proven, and they should be used in the context of a clinical trial. For consolidation most agree that hematopoietic stem cell transplantation (HSCT) with matched sibling donor is warranted for FLT3-ITD patients. There are not enough data to definitively recommend alternative donor transplantation in the absence of a matched sibling donor; however, it is not unreasonable to offer alternative donor HSCT given the poor prognosis of these patients.

and mortality with allogeneic transplant. Therefore an outstanding question is the identification of risk groups that benefit from matched related donor transplant. For those children with AML who have a relatively favorable prognosis after treatment with chemotherapy (e.g., t[15;17], t[8;21], inv[16], Down syndrome), it is reasonable to reserve HSCT for early relapse or second remission. Retrospective analysis of four cooperative group clinical trials by Horan et al showed no benefit for matched related donor transplant in the favorable-risk group patients.

In the same meta-analysis with intermediate-risk patients, there was a trend toward increase in 8-year OS in patients undergoing transplant versus chemotherapy alone (62% ± 7% versus 51% ± 5%, $P = 0.06$) due to decreased incidence of relapse. However, although AML99, NOPHO 93, MRC 10, and MRC 12 showed significant improvement in disease-free survival in patients with matched related donors, the OS difference was not significant. Many patients treated with chemotherapy alone in CR1 who relapsed could be salvaged. Therefore matched related donor transplant may be reserved for relapse in intermediate-risk patients, especially normal karyotype patients with wild-type FLT3 and CEBPA or NPM1 mutations that appear to confer favorable risk.

For poor-risk patients, outcomes for patients undergoing related HSCT was similar to chemotherapy alone. In AML02 high-risk patients with MRD greater than 1% after induction 1, HSCT showed a trend toward OS benefit (43% ± 12% versus 23% ± 10%, $P = 0.14$). Options for therapy intensification in poor-risk patients is limited, and most groups recommend transplant with matched related donor if available. Whether poor-risk patients benefit from alternative donor transplant (matched unrelated donor, cord blood) is not established. Recent advances have made the risk for toxicity with alternative donors approach that of matched related donors.

Although FLT3-ITD is a poor prognostic factor, whether to transplant based on the presence of FLT3-ITD alone is controversial. Data from MRC suggest that FLT3-ITD by itself is not a reason for transplant. In 683 adults comparing donor versus no-donor, the relapse risk was decreased if a donor was available and there was a trend toward benefit in OS, but this effect was seen in both FLT3-ITD and FLT3 wild-type AML. Data from COG showed that in individuals with a matched related donor, FLT3-ITD is no longer prognostic, suggesting that FLT3-ITD patients benefit from transplant. However, in this study by Meschinchi et al, 4-year OS comparison for FLT3-ITD patients in remission treated with HSCT versus chemotherapy alone was not significantly different (64% ± 29% versus 48% ± 17%, $P = 0.4$). It may be the case that FLT3-ITD patients benefit from allogeneic transplant, but larger studies of OS in pediatric patients with FLT3-ITD comparing transplant versus chemotherapy alone in intention-to-treat analysis and taking into account cytogenetic risk group are needed. Incorporation of other factors such as MRD may also help in identifying FLT3-ITD patients in need of transplant (see box on FLT3).

HSCT should be considered in first remission for children with high-risk features and be reserved for use in second remission or early relapse in all others. The decision to use HSCT for intermediate-risk patients in CR1 remains controversial. Up to 50% to 60% of patients with AML who achieve second remission and receive allogeneic transplantation appear to be long-term leukemia-free survivors. Patients with refractory disease or who relapse after intensive therapy within a year of diagnosis have a very poor prognosis with any form of therapy, including HSCT.

Myeloid Proliferations Related to Down Syndrome

Myeloid proliferations related to Down syndrome were recognized as a distinct category in the 2008 WHO classification of AML because of their unique genetic and clinical characteristics. These proliferations are seen as a transient abnormal myelopoiesis in neonates, and myeloid leukemia in young children. Some neonates with Down syndrome or trisomy 21 mosaicism may manifest a transient myeloproliferative disorder (TMD). This intriguing syndrome is diagnosed in 10% of neonates with Down syndrome, usually during the first week of life. TMD cannot be readily distinguished from congenital AML. The blasts have been shown to be clonal in origin, and there is complete clinical and hematologic recovery in approximately 80% of children with TMD within weeks to 3 months without therapy. Infants with TMD or transient leukemia may have very elevated

WBC counts with circulating blasts (megakaryoblasts or erythroblasts), hepatosplenomegaly, and an increased percentage of blasts in the bone marrow. There is a small subgroup of infants with TMD who die of liver failure and multiorgan system failure. In some of these patients, hepatic fibrosis is associated with megakaryoblast infiltration of the liver. Because the majority of infants with TMD never require any therapy in the first months of life, these neonates should be observed and given supportive care. However, for the small group of infants with liver failure or hydrops fetalis, a course of low-dose cytarabine may be helpful.

Data from retrospective surveys indicate that 30% of infants with TMD eventually develop AML (mostly AMKL) before 4 years of age. It is not known whether this is a recurrence of the original disease or the appearance of a new disease. Before the onset of AML, there is often a several-month prodrome characterized by thrombocytopenia and bone marrow myelofibrosis with dysplastic megakaryocytes. Mutations in the GATA-1 gene, an erythroid/megakaryoblastic transcription factor, are present in the blast cells from infants with TMD as well as patients with Down syndrome and AMKL.

An unexpected finding has been the high cure rate of AML in children with Down syndrome AMKL, including those who had TMD as neonates. This may in part be due to an increased in vitro sensitivity of Down syndrome myeloblasts to chemotherapy, especially cytarabine and daunorubicin. In in vitro studies with cytarabine, there is greater generation of ara-C triphosphate (ara-CTP) compared to myeloblasts from children without Down syndrome. Excellent results have been obtained with reduced-intensity therapy, with 91% OS in BFM trials, as compared to 56% survival in non–Down syndrome M7 AML. Reduced-intensity therapy is especially important because of increased susceptibility to anthracycline-induced cardiotoxicity in Down syndrome patients. Reducing chemotherapy is also advisable in Down syndrome AML patients because they appear to be more susceptible to treatment-related mortality, especially in intensive-timed regimens. Thus most cooperative groups treat Down syndrome AML on reduced-intensity regimens.

Therapy-Related AML

AML as a secondary malignancy after chemotherapy for another malignancy represents a difficult-to-treat subgroup of pediatric AML. Risk for therapy-related AML is primarily related to treatment with alkylating agents and epipodophyllotoxins. Common cytogenetic abnormalities include loss or deletions of chromosomes 5 and 7 and 11q23 MLL rearrangements. These patients are often heavily pretreated with ongoing morbidity from prior treatment. Complete remission rates in CCG-2951 were 50%, compared to 72% for de novo AML. OS in small series range from 14% to 26%. These patients should be treated with intensive induction therapy. There is little data comparing allogeneic stem cell transplant versus chemotherapy for consolidation, but in most reports survivors had undergone transplant.

Management of Relapse

The prognosis for children who do not enter remission with frontline chemotherapy or who suffer an on-therapy relapse is very poor. Intensive reinduction therapies and HSCT for second complete remission are associated with significant treatment-related morbidity and mortality. Chemotherapy options are sometimes limited due to cumulative anthracycline exposure. Many different chemotherapy regimens have been evaluated in children and adults with refractory or relapsed AML. Relapse regimens that have been investigated include high-dose cytarabine with L-asparaginase or mitoxantrone, etoposide (VP-16) and amsacrine with or without azacitidine, fludarabine and cytarabine, and 2-chlorodeoxyadenosine (2-CDA). Clofarabine is a nucleoside analogue that shows promise in relapsed leukemia as monotherapy or in combination with other agents. Other investigational agents include farnesyltransferase inhibitors, inhibitors of the mammalian target of rapamycin, kinase inhibitors, proteasome inhibitors, and epigenetic modifiers.

The best predictor of response to chemotherapy after relapse is the duration of the first remission. Children who relapse within 1 year after achieving remission have a substantially lower likelihood of achieving a second remission when compared with those patients who relapse later. The complete remission rate is 30% to 40% for the former group and 60% to 70% for the latter group. Fewer than 20% of the complete responders are projected to remain in remission for more than 2 years, unless they receive an HSCT.

The projected 5-year survival rate after an allogeneic or autologous HSCT in second remission is 40% to 60%. Because of the higher rate of relapse after an autologous compared to an allogeneic HSCT, there is growing experience with matched unrelated donor transplants using bone marrow or cord blood. In selected patients (short duration of first remission or early relapse), it is reasonable to undertake an HSCT without an attempt at inducing a second remission. This is feasible only if a transplant option is immediately available and the patient is clinically stable. A second transplant for multiply relapsed AML is feasible.

For relapsed patients without a matched related or unrelated donor, haploidentical transplants have become an option. Outcomes are typically worse compared to matched related transplants. However, mismatch at the KIR locus has been suggested to lead to improved outcomes in haploidentical transplants owing to NK cell alloreactivity. A subset of killer immunoglobulin-like receptors (KIRs) expressed on NK cells will inhibit NK cell function when engaged by specific major histocompatibility class I proteins. In HSCT, NK donor cells are thought to help eliminate recipient leukemia cells if the recipient cells do not express the cognate major histocompatibility epitope for the donor's inhibitory KIR. For matched unrelated transplants, the effect of KIR mismatch is not as clear.

Less than 5% of patients who achieve remission develop isolated CNS relapse. Risk factors for CNS relapse include age less than 2 years, hepatosplenomegaly, CNS disease at diagnosis, high WBC count, monocytic morphology, and chromosome 11q23 abnormalities. A COG study of 33 patients with isolated CNS relapse reported OS of 26%. Outcome following systemic versus local therapy was similar, suggesting that the rare patients with CNS relapse can be treated with local therapy alone, although this conclusion should be interpreted with caution because of the retrospective nature and small number of patients in this study.

FUTURE DIRECTIONS

The major challenge for the future is to continue improvement on all fronts for the care of patients with AML, including understanding the biology of the leukemic stem cell, disease classification, supportive care, development of more-effective therapies, and how to deliver the optimal combination of therapy for an individual patient. Although improved over past rates, the 5-year EFS rate is still only approximately 50% to 60%, and a substantial portion of children with AML continue to relapse and ultimately die of their disease. The primary cause of relapse is the development of drug resistance, and newer insights into the multiple mechanisms of drug resistance are beginning to be elucidated. Not to be overlooked is the importance of optimizing supportive care, because the treatment-related mortality with AML is still substantial.

Risk stratification and optimal treatment for different risk groups is a major issue. Current cytogenetics-based stratification schemes have identified good-risk patients (core binding factor leukemias, APL, and Down AMKL) but fare poorly in identifying intermediate-risk and high-risk patients who will ultimately relapse. Prospective incorporation of information on genetic mutations, MRD, gene expression, epigenetic profiles, and phospho-flow will better delineate at-risk patients. In most cases, these risk factors and their effect on prognosis will differ in pediatric versus adult AML.

Once patients are stratified, new therapies are needed that interfere with leukemia-related biologic processes. Lestaurtinib, a small-molecule inhibitor of FLT3, has selective toxicity against FLT3-ITD AML cell lines and in mouse models, but cells can develop resistance to FLT3 inhibition. Other FLT3 inhibitors are in various stages of development and clinical trials testing. Sorafenib is a Raf kinase inhibitor that also has activity against FLT3-ITD in vitro and in mouse models. The proteasome regulates the levels of many intracellular proteins, including NF- κB, and proteasome inhibition has been effective in myeloproliferative disorders. Bortezomib is a proteasome inhibitor that has in vitro activity and synergy with chemotherapeutic agents against primary AML cell lines. Regulation of epigenetic modifications with histone deacetylase and DNA methyltransferase inhibitors is also another promising area of research. Intriguing, novel efforts to screen libraries of small molecules based on their effect on gene expression signatures has yielded unexpected compounds active in promoting differentiation of AML. Antibodies targeting CD47-expressing leukemia stem cells are being developed. Many of these new agents are being tested up front in high-risk patients in a risk-adapted strategy and in the relapse setting. Eventually it may be possible to target the genetic lesions of leukemic cells in other AML subtypes, as exemplified by the use of ATRA in APL or imatinib in chronic myelogenous leukemia. In a completely different approach, the use of NK cells has been studied as a cell-based therapy outside of HSCT. NK cells from haploidentical donors, but mismatched at the KIR locus, can be isolated and infused into recipients and expanded in vivo using a combination of immunosuppressive agents and interleukin-2 to provide an antileukemia effect. This approach has been used to successfully maintain remission in low- and standard-risk patients treated with chemotherapy alone.

The improved ability to measure MRD by PCR, immunophenotyping, or specific genetic alterations should result in giving therapy when leukemic burden is smaller and selected intensification of therapy in the presence of residual leukemia. Through the development of new agents, improved monitoring, intelligent use of biologic response modifiers, and limiting the use of HSCT to high-risk patients, therapy can be closely tailored to improve outcome. For high-risk patients, the increasing availability of alternative sources of hematopoietic stem cells from unrelated bone marrow or cord blood donors will greatly expand the use of HSCT in all phases of therapy. Strategies based on preclinical models are also being developed that will hopefully achieve a more favorable balance of the graft-versus-host and graft-versus-leukemia reactions.

CHAPTER 62

MYELODYSPLASTIC AND MYELOPROLIFERATIVE NEOPLASMS IN CHILDREN

Franklin O. Smith and Mignon L. Loh

The myelodysplastic (MDS) and myeloproliferative neoplasms (MPN) are a heterogeneous group of clonal stem cell disorders that result in ineffective hematopoiesis and an increased risk of developing acute myeloid leukemia (AML). In children, MDS and MPN are now classified into three main groups: MDS, juvenile myelomonocytic leukemia (JMML), and transient myeloproliferative disorder (TMD) in children with Down syndrome. Whereas in MDS, ineffective hematopoiesis results in progressive cytopenias, in MPN, at least initially, ineffective hematopoiesis leads to excessive proliferation frequently characterized by increased peripheral blood counts. MDS and MPN are rare in children. Chronic myeloid leukemia (CML), characterized by the Philadelphia chromosome (*BCR/ABL* positive) is seen in both children and adults, but other forms of MPN (polycythemia vera [PV], essential thrombocythemia [ET], primary myelofibrosis [PMF], chronic neutrophilic leukemia [CNL], chronic eosinophilic leukemia [CEL], chronic basophilic leukemia [CBL], chronic myelomonocytic leukemia [CMML], systemic mastocytosis [SM], and stem cell leukemia–lymphoma syndrome [SCLL]) are exceedingly rare in children. Readers interested in CML and disorders that are predominantly found in adults are referred to in Chapters 59 and 66 to 69. In contrast, two MPNs are uniquely pediatric: JMML and Down syndrome-associated TMD.

MYELODYSPLASTIC SYNDROMES

The MDS are a heterogeneous group of disorders characterized by ineffective hematopoiesis, impaired maturation of hematopoietic cells, progressive cytopenias, and dysplastic changes in the bone marrow (BM).

Epidemiology

Myelodysplastic syndrome is a common malignancy of adults with an incidence of 50 cases per million in people older than the age of 60 years.[1] In contrast, MDS accounts for only 3% to 7% of all hematologic malignancies in children, with an unknown true incidence. Several population-based studies have been performed with reported incidences of 4.0 cases per million in Denmark,[2] 3.1 per million in British Columbia,[3] and 1.35 per million in the United Kingdom.[4] The median age of presentation is 6.8 years with an equal sex distribution.[4-6]

Pathobiology

As in adults, MDS in children can be considered as primary (de novo) or secondary. In adults, two predominant patterns of primary, de novo MDS have been observed. In the first of these patterns, the disease is indolent in nature and is characterized by prolonged survival, little accumulated genetic damage, and a low probability of progression to AML. This group of diseases is best exemplified by the 5q-syndrome, an entity not seen in children. Far more common in adults is a disease characterized by the accumulation of genetic damage, progression to BM failure, and a high probability of developing AML. This form of the disease is characterized as a mutator phenotype.[7] The primary myelodysplastic syndromes seen in children appear to share this mutator phenotype.

As in adults, secondary MDS in children can also arise as sequelae from exposure to chemotherapy and radiation; however, MDS in children may also result from constitutional BM failure syndromes including Fanconi anemia, severe congenital neutropenia (SCN), Shwachman-Diamond syndrome, congenital amegakaryocytic thrombocytopenia, dyskeratosis congenital. and Diamond-Blackfan anemia.

Ongoing studies are now defining the molecular pathogenesis and interrelationships among MDS, myeloproliferative syndromes (MPS), and AML.[8-10] Accumulating data suggest that aberrant signal transduction resulting from acquired somatic mutations encoding proteins leading to hyperactivation of the Ras pathway may stimulate proliferation without concomitant differentiation.[9] This has been clearly demonstrated in CML *(BCR-ABL)*.[11,12] A number of other putative pathogenetic mutations have been identified in other myeloproliferative disorders, including *JAK*2V617F mutations in PV, ET, and PMF[13]; *KIT*D816V mutations in SM[14]; *FIPL1-PDGFRA* in CEL-SM[15]; *ZNF198-FG4FR1* mutations in SCLL[16]; *RAS/NF1/PTPN11* mutations in JMML[17-19]; and *GATA1* mutations in TMD (Fig. 62-1).[20]

AML is the result of cooperating mutations in genes that confer a proliferative and survival advantage without effecting differentiation (e.g., activating mutations in receptor tyrosine kinases [FLT3, c-kit]) and genes that impair differentiation and apoptosis (e.g., loss of function mutations in transcription factors [CBF, AML/ETO]) (Fig. 62-2). This multistep model for the pathogenesis of AML is supported by murine models,[21,22] the analysis of leukemia in twins,[23-26] and the analysis of patients with familial platelet disorder with a propensity to develop AML (FDP/AML syndrome).[27] Finally, several mutations have been described in adult MDS that do not appear at all or are only rarely found to be present in children with MDS, including *TP53, CSF1R (FMS),*[28] *NRAS* and *KRAS2*.[29]

More recently, methylation studies in children with advanced MDS have demonstrated hypermethylation of the CDKN2B (p15) gene[30] or *CALCA* and *CDKN2B* genes.[31] Although the frequency of hypermethylation in children is similar to that seen in adults, the clinical significance of hypermethylation in children with MDS is not yet known. Finally, whole-genome sequencing of adult MDS samples revealed a high frequency of novel mutations in components of RNA spicing mechanisms.[32] The relevance of this unique finding to children with MDS is currently uncertain.

Classification

Until recently, MDS in children was poorly defined, characterized, classified, and reported. In fact, MDS was not included in the International Classification of Childhood Cancer until 2005.[33] Also contributing to this lack of information was the use of classification and prognostic systems designed for adults that have had limited applicability to children. A number of classification systems for children and adults have now been proposed. The most commonly used system is the French-American-British (FAB) system originally

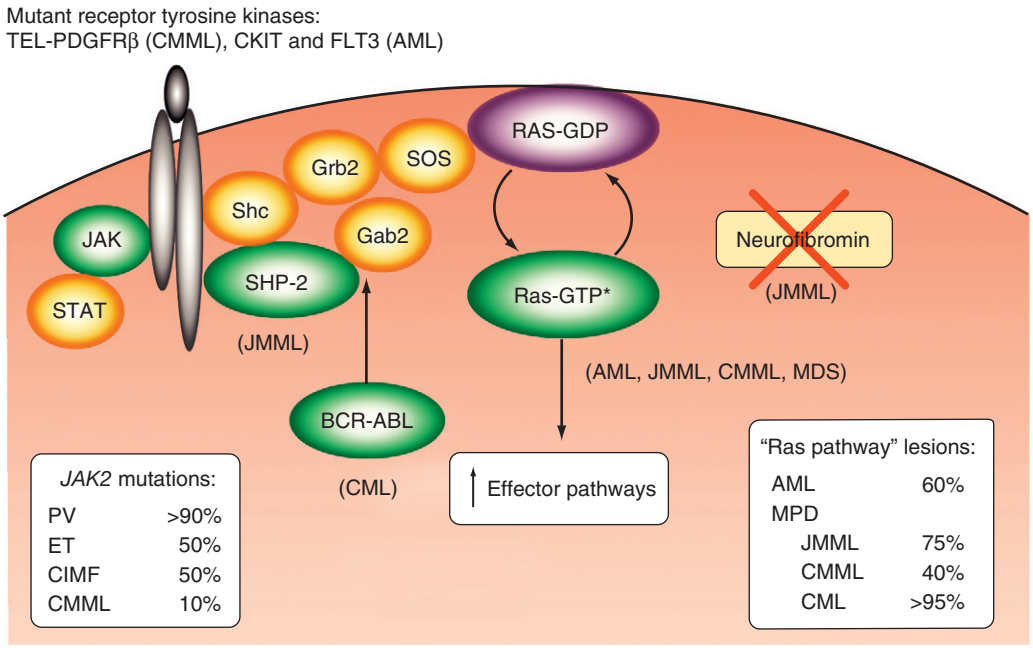

Figure 62-1 OVERVIEW OF RAS SIGNALING WITH MOLECULES HARBORING MUTATIONS IN PATIENTS WITH MYELOID MALIGNANCIES. *AML,* Acute myeloid leukemia; *CML,* chronic myeloid leukemia; *CMML,* chronic myelomonocytic leukemia; *ET,* essential thrombocythema; *GDP,* guanosine diphosphate; *GTP,* guanosine triphosphate; *JMML,* juvenile myelomonocytic leukemia; *MPD,* myeloproliferative disorder; *PV,* polycythemia vera.

proposed in 1982.[34] This classification system recognized five forms of MDS in adults: refractory anemia (RA), refractory anemia with ringed sideroblasts (RARS), refractory anemia with excess of blasts (RAEB), refractory anemia with excess of blasts in transformation (RAEB-T), and CMML. Using this system, whereas RAEB, and RAEB-T were commonly reported in children, RA and RARS were thought to be rare in children. However, a population-based study in the United Kingdom showed 25% of childhood MDS cases to be RA or RARS4 suggesting inaccurate diagnosis or reporting of these subtypes in other pediatric studies. CMML has only rarely been reported in children.

Table 62-1 Proposed Pediatric Myelodysplastic Syndrome Classification

I. COMBINED MYELOPROLIFERATIVE AND MYELODYSPLASTIC DISEASES
Juvenile myelomonocytic leukemia
Chronic myelomonocytic leukemia
BCR/ABC-negative chronic myeloid leukemia
II. DOWN SYNDROME DISEASE
Transient myeloproliferative disease
Myelodysplasia syndrome or acute myeloid leukemia
III. MYELODYSPLASTIC SYNDROME
Refractory cytopenias with multilineage dysplasia (RCMD)
RCMD-EB

Additional subtypes of MDS are now recognized that do not fit well into the FAB system, including hypoplastic MDS, therapy-related MDS, refractory cytopenias with trilineage dysplasia, MDS associated with myelofibrosis, and MDS associated with inherited disorders (congenital neutropenias, Shwachman-Diamond syndrome, Fanconi anemia), Down syndrome, neurofibromatosis type 1, and mitochondrial cytopathies.[35,36] Therefore, the World Health Organization (WHO) recently proposed changes to the FAB criteria to account for many of these subtypes.[37,38] Other significant changes included elimination of the RAEB-T subtype with reclassification of MDS with greater than 20% blasts as AML and reassignment of CMML and JMML to a new category of MDS/MPN.

Despite these improvements to the FAB system found in the WHO classification, there are still a number of limitations for children. Therefore, several pediatric-based classification systems for MDS and MPS have been proposed. Among these is a system to parallel the WHO classification (Table 62-1).[39] A second system based on category, cytology, and cytogenetics (CCC) allows for classification of individual patients into a very large number of

categories.[40] The clinical utility of this system is unclear. However, a comparison of these two pediatric systems with the adult WHO and FAB systems suggested that both were superior for children rather than the corresponding adult classification system.[41]

Taken together, it may be useful to think about childhood MDS as primary or secondary, with secondary MDS arising either from a known congenital BM failure syndrome or prior acquired aplastic anemia or as a complication from prior chemotherapy or radiation therapy. A diagnosis of primary MDS would then apply to all other cases.

Clinical Manifestations

Signs and symptoms of MDS are nonspecific and are usually attributable to pancytopenia (fever, infections, pallor, fatigue, bruising, and petechiae). Lymphadenopathy, hepatomegaly, and splenomegaly are uncommon presenting signs in children with MDS.

Laboratory Manifestations

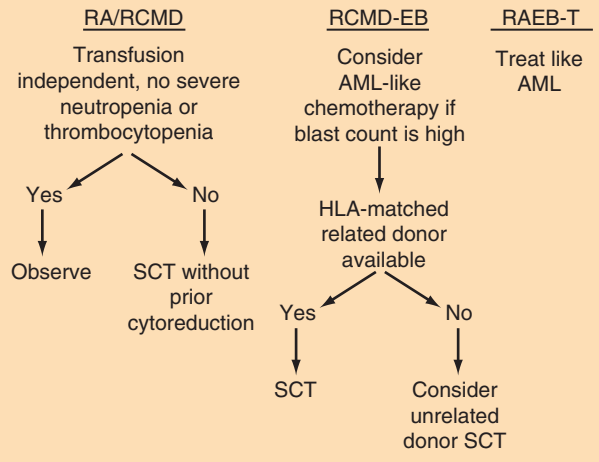
Commonly accepted minimal diagnostic criteria for pediatric MDS include the absence of common de novo AML karyotypic abnormalities and at least two of the following: (1) sustained, unexplained anemia; neutropenia or thrombocytopenia; dysplastic morphology in the erythroid; granulocytic or megakaryocytic lineages (at least bilineage) and (2) an acquired, sustained clonal cytogenetic abnormality and 5% or more blasts in the BM.[7,39] Almost half of all children with MDS in a series reported by Kardos et al[42] presented with refractory cytopenia, most notably neutropenia and thrombocytopenia.

Morphologically, the BM may be hypocellular, normocellular, or hypercellular. A diagnosis of MDS is made based on the presence of dysplastic changes in at least two cell lineages. The dysplastic changes in the granulocytes (hypogranulation, nuclear hyposegmentation, megaloblastoid maturation, and a left shift with an increased number of myeloblasts), megakaryocytes (micro-megakaryocytes, abnormal megakaryocyte nuclei), monocytes (increase in BM monocytes, abnormal granulation with persistence of azurophilic granules, hemophagocytosis, abnormal nuclei, and giant forms), or erythroid lineages (megaloblastoid maturation, nuclear budding and multinucleated forms, and ringed sideroblasts) can be multiple and varied. Similar dysplastic changes can occur in the peripheral blood for each of these lineages. Although dysplastic changes in the BM are a common feature of MDS, it is important to remember that dysplasia, unto itself, is not diagnostic of MDS because dysplastic features are associated with other conditions and can be found in normal BM donors.[43]

Although flow cytometric analysis can serve to quantitate the number of blasts based on aberrant cell surface antigen expression and detect populations of paroxysmal nocturnal hemoglobinuria (PNH)–like CD91 cells,[44] flow cytometric findings analysis is not generally diagnostic of MDS.

Cytogenetic abnormalities are seen in approximately half of children diagnosed with de novo MDS. Karyotypic abnormalities most commonly seen are –7, 7q–, and +8. Abnormalities in chromosomes 6, 9, 11, 12, and 13 are rare in children. Specific abnormalities seen in adults, including –5, 5q–, and –Y, are very rarely seen in children.

Differential Diagnosis



Although the history, physical examination, evaluation of the BM and peripheral blood, and cytogenetic analysis often make the diagnosis of MDS, other diseases should be considered. Congenital disorders such as Down syndrome, Fanconi anemia, Shwachman-Diamond syndrome, Diamond-Blackfan anemia, congenital dyserythropoietic anemias, and hereditary sideroblastic anemia should be considered. Hypoplastic MDS can be difficult to distinguish from severe aplastic anemia and may require prospective monitoring and serial BM examinations. The differential should also include AML with a low blast count, mitochondrial cytopathies such as Pearson syndrome, and myeloproliferative disorders. Specifically, PNH, although rare in children, should be considered. Deficiencies of vitamin B_{12} and folate can cause megaloblastic changes that resemble the dysplastic changes seen in MDS. Other nutritional deficiencies, including iron, thiamine, riboflavin, and pyridoxine, should be considered. Infections caused by human immunodeficiency virus, parvovirus, Epstein-Barr virus, cytomegalovirus, and human herpes virus 6 can cause changes that resemble MDS. Finally, the differential diagnosis should include toxins (insecticides, chemotherapy agents, and arsenic) as well as cytokine exposure and radiation. When the diagnosis is unclear, serial BM examinations may serve as a useful aid.

Therapy

Although MDS is a heterogeneous, clonal disease of hematopoietic stem cells that can manifest different clinical courses, it is not readily curable by conventional chemotherapy and requires allogeneic hematopoietic stem cell transplantation (SCT) for cure in most cases. Some children with RA and refractory cytopenias with multilineage dysplasia (RCMD) who do not have life-threatening neutropenia and who do not require transfusions may only require close observation (see box on Treatment Overview for Children With MDS). Although children with this disease may eventually develop progressive disease requiring SCT, they may have long periods when minimal treatment is required.[42] The use of AML-like chemotherapy for patients with RCMD with excess blasts (RCMD-EB) is controversial but may serve to "debulk" patients with a high percentage of blasts before SCT.[6,45,46] However, this potential benefit may be offset by toxicities associated with AML-like chemotherapy. Finally, patients with RAEB-T, which is now defined as AML, or t-MDS, should be treated like those with AML.

A multitude of agents have been studied for the treatment of MDS in adults but only rarely in children. These include low-dose chemotherapy (cytosine arabinoside, melphalan, hydroxyurea, etoposide, topotecan, 6-mercaptopurine, and busulfan), hormones (glucocorticoids and androgens), differentiating agents (13-*cis*-retinoic acid, all-trans retinoic acid), hematopoietic growth factors (granulocyte-macrophage colony-forming factor [GM-CSF], granulocyte colony-forming factor [G-CSF], and erythropoietin), demethylating agents (decitabine, 5-azacytidine), proteosome inhibitors, antiangiogenic agents, and arsenic.[47-62] The difficulty in assessing the safety and efficacy of new agents in children with MDS is illustrated by the Children's Oncology Group's (COG's) recent prospective study of amifostine.[63] This prospective phase II cooperative group study was unable to be completed due to lack of accrual. As a result, the safety

Treatment Overview for Children With MDS

and efficacy of amifostine in children with MDS remains uncertain. Finally, although the potential to better control MDS in adults with azacitidine, decitabine, and arsenic is exciting, there are currently no safety or efficacy data to support the use of these agents in children with MDS.

Most children with MDS require allogeneic SCT for curative therapy. Although children have been included in published SCT studies for MDS that are largely focused on adult patients, several studies focus specifically on children.[64-69] Taken together, these studies suggest a probability of disease-free survival in about 50% of patients undergoing human leukocyte antigen (HLA)–matched related donor SCT. The Center for International Blood and Marrow Transplant (CIBMTR) recently published results for 118 children with MDS who underwent unrelated donor SCT.[68] Forty-six children had refractory cytopenia (RC), 55 with RAEB and 17 with RAEB-t. Relapse of disease was most likely in children with RAEB and RAEB-t with transplant-related mortality and highest in recipients of HLA-mismatched grafts. The 8-year probabilities of disease-free survival for children with RC, RAEB, and RAEB-t were 51%, 35%, and 29%, respectively (Fig. 62-3).

Prognosis

Although a number of methods have been developed to predict the outcome of adults with MDS, the system now most commonly used in adults is the International Prognostic Scoring System.[70] This system uses percentage BM blasts, karyotype, and number of cytopenias to assign a score that is then used to predict outcome. Although it is an effective tool for adults, its value for children is very limited.[71]

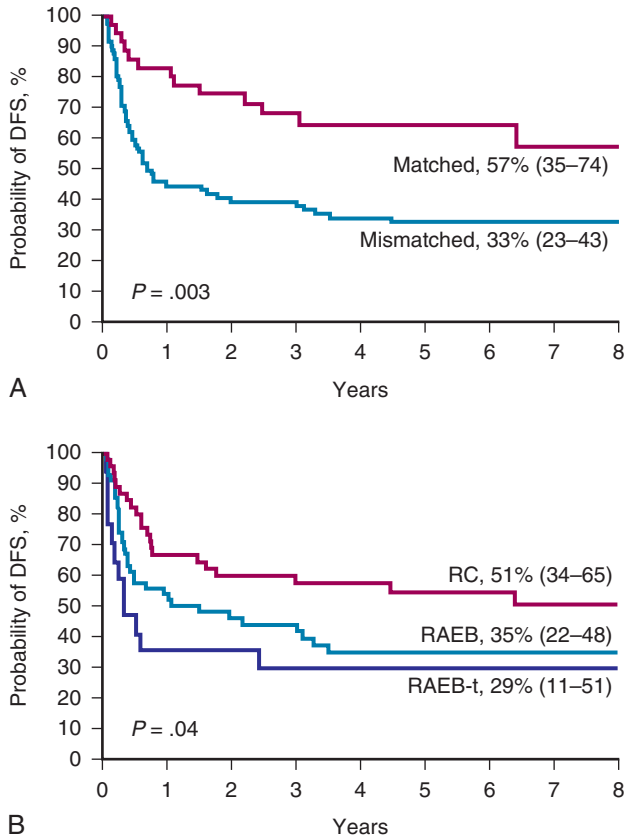


Figure 62-3 A, The 8-year probabilities of disease-free survival (DFS) after bone marrow transplantation (BMT): 57% for patients who received matched BMT (matched at human leukocyte antigen A, B, C, DRB1) and 33% for patients who received mismatched BMT. **B,** The 8-year probabilities of disease-free survival after BMT: 51% when transplantation was performed for RC, 35% when transplantation was performed for refractory anemia with excess of blasts (RAEB), and 29% when transplantation was performed for refractory anemia with excess of blasts in transformation (RAEB-T). *(Reproduced with permission from Woodard P, Carpenter PA, Davies SM, et al: Unrelated donor bone marrow transplantation for myelodysplastic syndrome in children.*Bio Blood Marrow Transplant *17: 723, 2011.*

Secondary Myelodysplastic Syndrome

Secondary MDS can develop in both children and adults after exposure to chemotherapy and radiation. Alkylating agents used to treat Hodgkin disease, non-Hodgkin lymphoma, and Ewing sarcoma are particularly concerning in children.[72-84] Interestingly, there is also evidence to suggest that the cardioprotectant dexrazoxane, a topoisomerase II inhibitor with a mechanism of action that is different from etoposide and doxorubicin, may have increased the incidence of secondary MDS and AML in children treated for Hodgkin disease.[85]

Treatment options for children with secondary MDS are limited. Although AML-like chemotherapy can induce a period of remission and reduction in BM blasts, it is not curative. Allogeneic SCT has curative potential, but outcomes remain poor, with only 20% to 30% of children surviving in reported series.[83,86,87] However, as noted earlier, recent data from the CIBMTR demonstrate that treatment failure with unrelated donor SCT is not higher compared with primary MDS.[68]

MYELOPROLIFERATIVE NEOPLASMS

Juvenile Myelomonocytic Leukemia

Juvenile myelomonocytic leukemia is classified by the WHO as an overlap MDS and MPN. It is an aggressive myeloid malignancy of young children with poor outcomes to conventional therapies. The diagnostic criteria are complex (Table 62-2), but recent advances in elucidating the molecular genetics of the disorder demonstrate that approximately 85% of children will harbor an alteration in one of five genes. Thus there is now international agreement on the diagnostic criteria[88] (see Table 62-2) with an emphasis on incorporating these molecular genetic criteria, and there is also recent progress toward defining common response criteria.

Table 62-2 Diagnostic Criteria for Juvenile Myelomonocytic Leukemia

CATEGORY 1 *All of the following:*	CATEGORY 2 *At least 1 of the following:*	CATEGORY 3 *At least 2 of the following:*
• Splenomegaly*	• Somatic mutation in *RAS* or *PTPN11*	• Circulating myeloid precursors
• Absolute monocyte count (AMC) > 1000/μL	• Clinical diagnosis of NF1 or *NF1* gene mutation	• WBC > 10,000/μL
• Blasts in PB/BM < 20%	• Homozygous mutation in *CBL*	• Increased fetal hemoglobin (Hgb F) for age
• Absence of the t(9;22) *BCR/ABL* fusion gene	• Monosomy 7	• Clonal cytogenetic abnormality excluding monosomy 7
		• GM-CSF hypersensitivity

From Chan RJ, Cooper T, Kratz CP, et al: Juvenile myelomonocytic leukemia: A report from the 2nd International JMML Symposium. *Leuk Res* 33:355, 2009. The diagnosis of JMML is made if a patient meets all of the Category 1 criteria and one of the Category 2 criteria without needing to meet the Category 3 criteria. If there are no Category 2 criteria met, then the Category 3 criteria must be met.
*For the 7-10% of patients without splenomegaly, the diagnostic criteria must include all other features in Category 1 AND one of the parameters in Category 2 OR no features in Category 2 but two features in Category 3.

Epidemiology

The incidence of JMML in the United States has been estimated as 0.69 to 1.2 per million,[4,89] although its true incidence is currently not known, likely because of previous diagnostic imprecision. With the advent of molecular testing, the true incidence of this disease will be established in the coming years. There is a male predominance with a median age of diagnosis of 1.8 years.

Pathogenesis

Early clonality studies suggested that JMML arose at the level of at least an immature myeloid precursor cell.[88,90-94] More recent data suggest that JMML may arise in a pluripotent stem cell with involvement of the myeloid, erythroid, and megakaryocyte lineages as well as B lymphocytes and T lymphocytes.[88,95-97]

Several potential causative mutations in JMML cells have been identified, including loss of heterozygosity of NF1 in the context of patients with clinical neurofibromatosis 1 (15%),[98] activating RAS mutations (25%),[99,101] mutations in the *PTPN11* gene (see Fig. 62-1) (35%), and newly described mutations in *CBL* (10%–15%).[102-105] The identification of potential molecular mechanisms involved in the pathogenesis of JMML has been facilitated by two common human diseases (neurofibromatosis type 1 *[NF1]* and Noonan syndrome *[PTPN11]*) in which affected children are at a higher risk of developing JMML or a JMML-like MPN, and recent work demonstrates that children with germline CBL alterations also are at risk for developing JMML.

Approximately 10% to 15% of patients with JMML have clinically evident NFI,[88,98,106-108] and children with NF1 have a 500-fold increase in clonal malignant myeloid diseases, including JMML. The observation that individuals with NF1 are predisposed to JMML, the high incidence of *RAS* mutations in human cancers, and the identification of neurofibromin as a negative regulator that functions as a GTPase-activating protein that hydrolyzes Ras from its active GTP-bound state[88,109-111] led to the hypothesis that activation of the Ras–MAPK (mitogen-activated protein kinase) pathway plays a key role in the pathogenesis of this disease. Indeed, the demonstration of loss of heterozygosity of the wild-type *NF1* allele in leukemic cells from children with NF and JMML supports the observation that *NF1* functions as a tumor suppressor gene in myeloid malignancies. The mechanisms leading to loss of heterozygosity (LOH) of *NF1* in patients with JMML is unclear but is uniformly associated with the presence of acquired isodisomy of the mutant *NF1* allele.[112] In addition, accumulation of activated Ras proteins in these cells has provided evidence that the loss of *NF1* leads to excessive signaling downstream from Ras.[18,108,113,114] Abnormalities in *NF1* are also detected in an additional small percentage of JMML patients who do not display clinical manifestations of neurofibromatosis.[88,113] This finding is generally mutually exclusive of RAS mutations that occur in another 25% of patients, suggesting that both *NF1* and RAS mutations are sufficient to initiate JMML.[88,96,99,113,115,116-119] Indeed, accurate murine models of JMML have been engineered by several groups in which either the *NF1* gene has been homozygously deleted[120] or canonical *Nras* or $Kras^{G12D}$ or $Ptpn11^{E76K}$ alterations conditionally expressed.[121-123] The E76K knock-in mutation is embryonic lethal, but conditional expression of this allele results in a fatal MPN. One hallmark feature of human JMML is selective hypersensitivity of myeloid progenitors to low doses of GM-CSF in colony forming unit–granulocyte macrophage assays (CFU-GM), which is recapitulated in the mouse models and which is also associated with hyperactivation of the Ras–MAPK pathway as evidenced by increased levels of pERK. In 2001, Tartaglia et al[124] reported that constitutional mutations in *PTPN11* were causative of 50% of cases of Noonan syndrome (NS). NS is a common congenital disorder, with both acquired and sporadic forms. Patients affected by NS have cardiac defects (pulmonic stenosis of hypertrophic cardiomyopathy), variable levels of developmental delay, skeletal defects, and bleeding diatheses. Some children develop a JMML-like MPN in infancy that generally spontaneously recovers, although rare patients require chemotherapy or progress to frank JMML. Based on the knowledge that *PTPN11* encodes SHP-2, a nonreceptor protein tyrosine phosphatase that relays signals from activated growth factors to Ras, it was logical to hypothesize that somatic mutations in *PTPN11* might exist in the remaining cases of de novo JMML patients who did not have either clinical NF1 or harbor a RAS mutation. Indeed, 35% of patients with JMML were discovered to have mutations in *PTPN11* in residues altering the interaction between the N-SH2 and C-SH2 domains, leading to constitutive activity of the phosphatase.[17,102]

In 2009, Loh and colleagues[125] used single nucleotide polymorphism arrays to detect acquired isodisomy in a region of 11q in a subset of patients with JMML who did not have a known Ras pathway alteration. This led to the subsequent discovery of homozygous mutations in *CBL,* an E3 ubiquitin ligase that also serves as an important adaptor protein, as a fourth locus for genetic alterations in JMML.[103,105,125,126] Together with colleagues from the European Working Group on Childhood Myelodysplastic Syndromes, they then described that homozygous mutations in *CBL* first arise as germline events, with subsequent reduction to homozygosity in hematopoietic cells, in contrast to the lesions described in adults.[104] Specific germline features are found in the syndrome, although are not fully penetrant, and include cryptorchidism, hearing loss, and skeletal abnormalities. Analysis of family pedigrees indicate that transmission is autosomal dominant, although 50% of cases arise as spontaneous mutations. Others have confirmed these findings but in smaller series.[127,128]

Taken together, the early genetic data suggested that deregulated Ras–MAPK signaling is a common feature of JMML, which has been supported by mouse modeling. The interactions between SHP-2 (the protein encoded by *PTPN11*) and *CBL* and the Ras–MAPK pathway have yet to be fully elucidated, but the mutual exclusivity of mutations in *NF1,* RAS, *PTPN11* and *CBL* remain supportive of the hypothesis that these lesions are functionally redundant and that their common biochemical output is hyperactivation of the Ras–MAP kinase pathway.

Clinical Manifestations

Children with JMML present with signs and symptoms attributable to a heavy cell burden of organ-infiltrating cells that results in hepatosplenomegaly, lymphadenopathy, and skin rash. As a result of the association with neurofibromatosis, patients may also have café-au-lait spots or juvenile xanthogranulomas. Death is usually the result of organ dysfunction caused by infiltrating cells, infection, or bleeding. Approximately 10% to 20% of children progress to a blastlike phase consistent with AML.

Laboratory Manifestations

Laboratory abnormalities may include an elevated white blood cell count with an absolute monocytosis, anemia, and thrombocytopenia (Figs. 62-4 and 64-5). Monocytes, either circulating in the peripheral blood or in the BM, frequently appear dysplastic. The peripheral smear shows leukoerythroblastic changes, and there are often circulating nucleated red blood cells. Fifty percent of patients may also present with elevated fetal hemoglobin levels and hypergammaglobulinemia, which is of interest given that there are patients recently described with autoimmune lymphoproliferative syndromes who also harbor mutations in RAS, thus raising additional questions about other childhood BM disorders in which Ras–MAPK signaling is integral to pathogenesis. International criteria mandate that the BM has fewer than 20% blast cells at diagnosis. Other findings typical in the BM may include micro-megakaryocytes.

Differential Diagnosis

Traditionally, establishing a diagnosis of JMML was not easy because its clinical and laboratory presenting features can also be associated

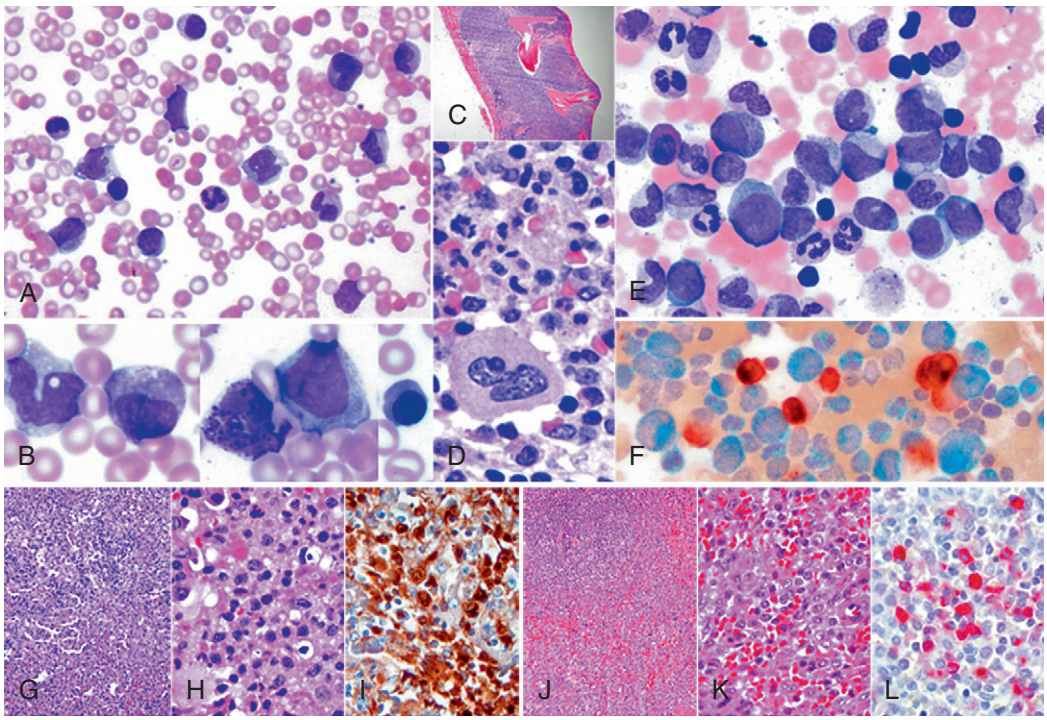

Figure 62-4 JUVENILE MYELOMONOCYTIC LEUKEMIA (JMML): BLOOD, BONE MARROW, LUNG, AND SPLEEN. The illustrations are from the case of a 3-year-old boy who was diagnosed with neurofibromatosis at birth. At 1 year of age, he presented with leukocytosis (58 K/μL). The peripheral blood (**A** and **B**) showed left-shifted granulocytes and increased monocytes (16%). A bone marrow biopsy (**C** and **D**) was hypercellular as a result of increased granulocytic and monocytic cells that could also be appreciated on the aspirate **(E)**. Blasts accounted for only 4% of the bone marrow elements. A combined esterase reaction (**F**) illustrated the increased monocytes (α-naphthol butyrate esterase reaction positive; *orange/brown*) in the background of granulocytes (chloroacetate esterase reaction positive; *blue*). Cytogenetic analysis revealed monosomy 7. At age 2 years, the patient presented with respiratory distress, and a lung biopsy (**G** and **H**) demonstrated a monocyte infiltrate (lysozyme stain, **I**) consistent with involvement by JMML. This is not uncommon in such patients. At age 3 years, his blast count began to rise, and he underwent a splenectomy (which showed a marked infiltrate of immature and mature monocytes and granulocytic cells (**J** and **K**; lysozyme stain, **L**). After the splenectomy the patient underwent a successful stem cell transplant.

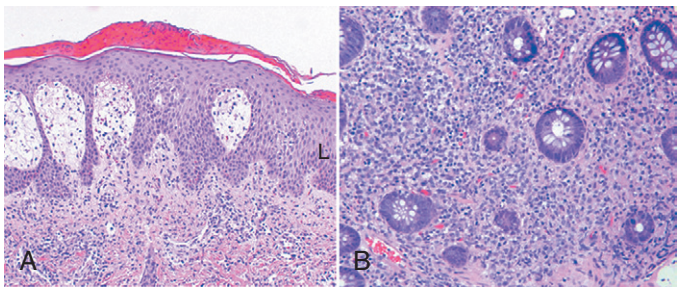

Figure 62-5 JUVENILE MYELOMONOCYTIC LEUKEMIA (JMML): SKIN AND GASTROINTESTINAL TRACT. Patients with JMML sometimes present with or develop skin nodules, which on biopsy show a myelomonocytic infiltrate in the upper and lower dermis **(A)**. Involvement can also be seen in the gastrointestinal tract **(B).** *(The case was kindly provided by Dr. Elizabeth Hyjek, University of Chicago.)*

with other disorders, including infections (Epstein-Barr virus, cytomegalovirus, human herpes 6 virus, histoplasmosis, mycobacterium, and toxoplasmosis), class I Langerhans cell histiocytosis, hemophagocytic lymphohistiocytosis, Fanconi anemia, Kostmann syndrome, Shwachman syndrome, and Down syndrome. However, with a positive molecular mutation, patients who exhibit the category 1 features are now more easily diagnosed.

Therapy

Children with JMML can have a variable course, with rare patients having a spontaneous remission and long-term survival without treatment but others having a rapidly fatal course despite aggressive treatment.[129,130] Age, platelet count, and hemoglobin F level have been used to predict the clinical course of patients not undergoing SCT,[116] but biologic features that can reliably predict an individual patient's clinical courses are not currently known. Currently, the most adverse prognostic factor for outcome is older age at diagnosis.[131]

A wide variety of agents have been used to treat children with JMML, including AML-like chemotherapy,[46,107,132-136] low-dose chemotherapy,[137,138] interferon-α,[139] and 13-*cis*-retinoic acid.[110] Tipifarnib, a farnesyl transferase inhibitor, was tested in a phase II window by the COG. Although the evaluation of these treatment regimens has been complicated by a lack of consistent response criteria and assays to measure the burden of clonogenic JMML stem cells, the efficacy of chemotherapy appears to be limited. Allogeneic SCT offers the only known potential for cure, with about half of transplanted children surviving disease-free.[131,140] Rapid withdrawal of immunosuppression appears to be important in this disease, as mounting evidence supports a graft-versus-leukemia effect.[141] A number of issues related to SCT for JMML remain uncertain. Among these are the value of pretransplant splenectomy and the optimal conditioning regimen and graft-versus-host disease prophylaxis. In the absence of data to suggest superiority of radiation containing preparative regimens, most transplants now occur with chemotherapy-only preparative regimens. The

most common cause of death after SCT is recurrent disease. A second SCT can be lifesaving for some children.[142,143] Donor leukocyte infusions are not often successful.[144]

Down Syndrome–Associated Transient Myeloproliferative Disorder

Epidemiology

Down syndrome is one of the most common congenital disorders, affecting approximately one in every 800 to 1000 live births. It has been demonstrated in a recent population-based study that children with Down syndrome have a 10- to 20-fold overall increased risk of developing leukemia,[145] a 150-fold increased risk of developing AML, and a 500-fold increased risk of acute megakaryocytic leukemia (AMKL). The median age of diagnosis of AMKL in individuals with Down syndrome is 2 years.[146] Transient myeloproliferative disorder, also known as transient abnormal myelopoiesis and transient leukemia, is thought to occur in at least 10% of children with Down syndrome, although it has been suggested that when cases of TMD that develop and resolve in utero or result in death before delivery are taken into account, the incidence may be as high as 20%.[147] Currently, it is estimated that approximately 20% to 30% of children with TMD subsequently develop AML, usually by 3 years of age. This estimate was validated in a recent prospective study conducted by the COG.[148] In this study, AML developed in 16% of Down syndrome children who had TMD at a median of 441 days (118-1085 days).

Pathobiology

The molecular pathogenesis of TMD and AMKL in children with Down syndrome is now providing valuable insights into myeloid leukemogenesis.[20] Recent studies have shown that virtually all patients with TMD and most patients with AMKL harbor mutations in the hematopoietic transcription factor *GATA1*.[149-153] *GATA1* is a double zinc finger DNA-binding transcription factor expressed primarily in hematopoietic cells. It is required for the development of red blood cells, megakaryocytes, mast cells, and eosinophils. A number of different mutations in *GATA1* have been identified, including insertions, deletions, missense mutations, nonsense mutations, and slice site mutations. All of these mutations lead to a block in the expression of the full-length 50-kd isoform of *GATA1* but allow for the expression of a smaller, 40-kd isoform *(GATA1s)*.[154] This smaller isoform lacks the N-terminal transactivation domain but retains both zinc fingers involved in DNA binding as well as interactions with its cofactor, friend of *GATA1* (FOG1).[149] Recent studies have shown that mutations that alter *GATA1–FOG1* binding in the N-terminal zinc finger or result in the expression of the *GATA1s* isoform uncouple megakaryocyte growth and differentiation.[155-157] Similar studies in cell lines derived from children with Down syndrome and AMKL have demonstrated that expression of *GATA1* led to erythroid differentiation whereas expression of *GATA1s* did not alter the characteristics of the cell line.[153] Taken together, current data suggest that the loss of *GATA1* and expression of *GATA1s* directly contribute to leukemogenesis. Although mutations in GATA1 may be sufficient to cause TMD, these mutations are not sufficient for the development of AMKL, as evidenced by the latency period between resolution of TMD and the development of AMKL as well as the observation that not all children with TMD and *GATA1* mutations will ultimately develop AMKL. Therefore, a multistep pathogenesis model is proposed in patients with Down syndrome in whom AMKL develops in clones with *GATA1* mutations and additional cooperating mutations. One potential "second-hit" mutation may occur in the JAK3 (Janus kinase 3) gene, a member of the JAK family of nonreceptor tyrosine kinases. Several gain-of-function mutations[158,159] and loss-of-function mutations in JAK3[160160] have been identified in both TMD and AMKL patient samples. Although mutations in *JAK3* might indeed represent a "second hit," the finding of mutations in TMD patients who have not progressed to AMKL may argue against *JAK3* as a second cooperating mutation.

Another particularly important area of investigation is the interaction between *GATA1* and chromosome 21. Identification of critical interactions between *GATA1* and relevant genes on chromosome 21 will serve to further inform us about the pathogenesis of leukemia in children with Down syndrome.

Clinical Manifestations

Patients with Down syndrome typically present with TMD within 3 months after birth, although TMD can be manifest at birth. Some of these children present with hydrops fetalis secondary to anemia and cardiac dysfunction. Although some patients may be asymptomatic, others can have myeloblast infiltration of the heart, liver, and spleen that can result in hepatosplenomegaly; hepatic fibrosis; pleural, pericardial, and peritoneal effusions; and disseminated intravascular coagulopathy. In some cases, organ dysfunction can be severe, with failure of the liver, heart, kidneys, and lungs. In the COG's recently published prospective study, death occurred in 21% of patients, although only 10% died as a result of TMD-associated problems.[148]

Laboratory Manifestations

The complete blood count in infants with TMD typically demonstrates an elevated white blood cell count with myeloblasts present (see Fig. 62-6). The percentage of circulating myeloblasts exceeds the percentage of BM myeloblasts. Rarely, a neonate without stigmata of Down syndrome will present with similar features—in these cases, workup for either trisomy 21 mosaicism or a PTPN11 mutation should be pursued. Flow cytometric analysis of the myeloblasts from TMD patients and AMKL associated with Down syndrome show many similarities between these disorders as well as patterns of cell surface antigen expression that is distinct from other types of AML in children.[161] Specifically, all TMD and AMKL blasts express CD45, CD38, and CD33, but the majority of cases express CD36 and CD34. CD41 and CD61 also are expressed, consistent with megakaryocyte differentiation. CD14 and CD64 are usually negative. Most cases have aberrant expression of CD7, a T-lineage antigen.

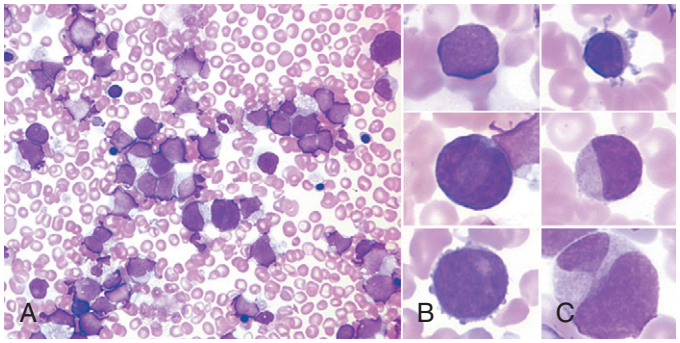

Figure 62-6 TRANSIENT MYELOPROLIFERATIVE DISORDER (TRANSIENT ABNORMAL MYELOPOIESIS AND TRANSIENT LEUKEMIA) OF DOWN SYNDROME. The patient was a premature newborn girl with trisomy 21 and a white blood cell count of 195,000/μL with 67% blasts **(A)**. The blasts were $CD34^+$, $CD33^+$ and $CD117^+$, and a portion exhibited CD41, a megakaryocyte marker. Morphologically, some of the blasts appeared to be megakaryoblasts **(B)**, sometimes with slight differentiation toward megakaryocytes **(C)**.

Therapy

The treatment of infants with TMD is generally supportive. Patients without significant organ dysfunction can be followed closely without medical intervention. In the COG's prospective study, peripheral blood blasts and TMD-associated symptoms resolved in 36 and 49 days, respectively, for observation patients.[148] In infants with significant organ impairment, a number of therapeutic approaches aimed at reducing the burden of myeloblasts are routinely used, including exchange transfusion, leukophoresis, and chemotherapy. According to reports using cytosine arabinoside in children with Down syndrome and AMKL,[162,163] cytosine arabinoside is the chemotherapeutic agent now most commonly used in infants with TMD. The efficacy of very low doses of cytosine arabinoside is being tested in prospective clinical trials. Several additional questions related to the treatment of infants with TMD are also the subject of ongoing clinical trials. Among these is the identification of high-, intermediate-, and low-risk populations with treatment stratified on the basis of risk group and a determination of whether treatment with very low dose cytosine arabinoside will prevent progression of TMD to AMKL and hepatic fibrosis.

Prognosis

Recent data from the COG reporting the results of the POG 9481 prospective clinical trial offer insights into the natural history of TMD and the identification of prognostic factors.[149] This study followed 48 children with TMD. Eighty-nine percent of infants achieved a spontaneous remission, 74% had a normalization of peripheral blood counts, and 64% maintained a clinical remission. Seventeen percent of infants had an early death. Factors associated with early death included a high white blood cell count (P <.001), increased bilirubin and liver function test values (P <.005), and a failure to normalize blood counts (P < .001). Nineteen percent of patients had a progression to AMKL at a median of 20 months. The greatest risk factor for progression to leukemia was the presence of karyotypic abnormalities in addition to trisomy 21 in blasts cells.

The COG's more recent A2971 study identified three groups of children with different outcomes based on the presence or absence of hepatomegaly and life-threatening symptoms.[148] Children with neither hepatomegaly nor life-threatening symptoms were at low risk of death (overall survival [OS], 92%); children with hepatomegaly alone had an intermediate risk of death (OS, 77%), and children with both hepatomegaly and life-threatening symptoms were at high risk of death (OS, 51%).

OTHER MYELOPROLIFERATIVE NEOPLASMS

Essential Thrombocythemia

Essential thrombocythemia has an estimated incidence of 1 to 1.25 cases per million in adults but is even rarer in children, with an estimated incidence of 0.09 cases per million.[165-169] Recent investigations in children and adults suggests that ET is a heterogeneous disease. Recently, mutations in *JAK2* have been reported in adults with *BCR-ABL*–negative MPNs, including ET, PV, and idiopathic myelofibrosis (IM). It has been proposed that ET consists of several subtypes, with some children and adults having monoclonal disease but others having polyclonal disease. Further investigation into the mutational status of V617F*JAK2* also demonstrates mutation-positive and -negative patients.[166,170] Studies suggest that a similar proportion of children and adults with somatic ET display polycythemia rubra vera-1 (PRV-1) RNA overexpression, V617FJAK2 mutations, and monoclonal disease.[171] Dominant activating mutations in c-MPL have been reported in rare cases of familial ET as opposed to JAK2 lesions.[171]

Patients with ET have thrombocythemia with an increased number of megakaryocytes in the BM. Platelet clumps on peripheral blood smears are common. Some patients have a concomitant increase in the number of peripheral blood granulocytes. The differential diagnosis includes familial ET (characterized by the dominant-positive activating mutation of *c-mpl*), other forms of MPS, and increased platelets as a reactive process.

Although the clinical course can be uncomplicated, patients can develop thromboembolic complications, including deep venous thrombosis, transient cerebral ischemia, and peripheral vascular ischemia. The clinical course for children is typically less aggressive than in adults, with fewer thrombotic episodes.[171,172] Adult patients have a median survival of at least 10 years, with most deaths caused by thrombosis.[173,174] Progression to AML has been reported in adult patients, usually those with a prior exposure to chemotherapy agents.

Asymptomatic children do not require treatment. A number of treatment approaches aimed at controlling thrombocytosis have been attempted for symptomatic patients, including hydroxyurea, interferon-α, and anagrelide.[175-177] The successful use of allogeneic BM transplantation has been reported for a small number of adult patients with ET.[178,179] Newer JAK2 inhibitors for patients harboring *JAK2* mutations are in the early phases of clinical development.

Idiopathic Myelofibrosis

Idiopathic myelofibrosis is rarely diagnosed in children[180] and should be differentiated from AMKL; metastatic neoplasms; and connective tissue, metabolic, and bone diseases. It is characterized by BM fibrosis, megakaryocytes with bizarre morphology, splenomegaly, anemia, and extramedullary hematopoiesis. IM is a clonal disorder with approximately half of adult patients having mutations in V617FJAK2.[181] Recent studies have suggested that angiogenic cytokines produced by megakaryocytes and monocytes and their receptors (platelet-derived growth factor receptors [PDGF-R], vascular endothelial growth factor receptor-2 [VEGF-R2] and fibroblast growth factor [FGF] receptor), may be involved in the pathogenesis of the myelofibrosis.[182]

Numerous treatment approaches have been attempted with variable degrees of success. These include splenectomy, splenic radiation, transfusions, androgens, corticosteroids, hydroxyurea, and interferon-α.[183-185] More recently, based on preliminary studies about the potential role of angiogenic cytokines and their receptors, new approaches have been tested, including the tyrosine kinase inhibitor imatinib[186,187] and the antiangiogenic agent thalidomide.[188,189] Selective JAK inhibitors have been successfully used in patients with IM with a dramatic improvement in the quality of life but without generalized reduction of the V617F JAK2 burden allele.[190] The U.S. Food and Drug Administration recently granted approval to the first of these agents, ruxolitinib, for adults with IM. However, the safety and efficacy of ruxolitinib in children is currently unknown. Finally, allogeneic transplantation has been used successfully, with resolution of BM fibrosis in donor-engrafted patients.[179,191,192] The survival in children is unknown with a median survival in adults of 4 years.

Polycythemia Vera

Polycythemia vera has an incidence of three cases per 100,000 in adults but is very rarely seen in children with fewer than 0.1% of PV patients diagnosed before 20 years of age.[193] PV in children is far more often the result of congenital or acquired causes of an increased red blood cell mass. These include primary familial polycythemia (characterized by specific mutations in the thrombopoietic gene [TPO], TPO receptor, or erythropoietic receptor gene) and secondary polycythemias caused by abnormal hemoglobins, cardiac and pulmonary disease, excessive erythropoietin, and a relative polycythemia that is the result of decreased plasma volume.

Polycythemia vera in children and adults is associated with clonal hematopoiesis,[194] V617F*JAK2* mutations,[171,195-199] overexpression of PVR-1 RNA,[200,201] and endogenous erythroid colony (EEC) growth.[202,203] However, in contrast to adults, children with PV are less

likely to have V617F*JAK2* mutations and EEC growth.[171] Thus, although these biomarkers are useful diagnostic tools in adults, thereby necessitating a revision to the WHO's diagnostic criteria,[204] they may not be as helpful in the diagnosis of PV in children. Although the pathogenesis is currently unclear, patients also have abnormalities in tissue factor, endogenous anticoagulants mechanisms, hyperhomocysteinemia, and acquired von Willebrand syndrome.

Children with PV may present with signs and symptoms associated with an increased red blood cell mass such as headache, dizziness, fatigue, pruritus, night sweats, and a ruddy complexion. Hepatosplenomegaly may be present. As a result of hyperviscosity of the blood, elevated platelet counts, and coagulation abnormalities, patients can develop thromboses and central nervous system ischemia, although the incidence of thrombotic events may be lower than that reported in adults.[171]

Many different agents have been used to treat patients with PV, including chlorambucil,[205] melphalan,[206] 6-thioguanine,[207] uracil mustard,[208] busulfan,[209] carboquone,[210] anagrelide,[211] imatinib,[212] hydroxyurea,[213] radioactive phosphorous,[214] and interferon.[215] A total of seven randomized clinical trials have been conducted in adults using some of these agents.[216] Despite these efforts, the best approach to patients with PV remains unclear. Therefore, the British Committee for Standards in Haematology recently formulated recommendations for the initial management of PV.[217] Recommendations include phlebotomy to maintain a hematocrit level less than 45% aspirin unless contraindicated; and cytoreduction if there is poor tolerance to phlebotomy, symptomatic or progressive splenomegaly, evidence of disease progression, or thrombocytosis. For patients younger than 40 years of age, interferon was the recommendation for first-line cytoreduction with hydroxyurea and anagrelide as second-line. Currently, JAK inhibitors are in early phase clinical trials to determine maximally tolerated doses and have been well tolerated thus far. Finally, allogeneic transplantation has been successfully used to treat a limited number of adult patients.[178,179,218,219] Allogeneic transplantation is considered only for patients with significant thrombotic disease or progression to AML.

FUTURE DIRECTIONS

Although a clearer understanding of the biologic mechanisms underlying MDS in children is slow in coming, dramatic progress has been made in our understanding of the genetic and biologic mechanisms contributing to TMD, JMML, PV, ET, and IM. There exists a potential for targeted therapeutics for many of these disorders, with the first targeted agents now receiving approval for use in adults. However, the use of these agents in children remains investigational.

Progress for both MDS and MPN in children will require international cooperation. The rarity of these disorders and limitations in resources for pediatric cooperative cancer groups make clinical trials within each individual cooperative group increasingly difficult.

CHAPTER 63

PATHOBIOLOGY OF ACUTE LYMPHOBLASTIC LEUKEMIA

Alejandro Gutierrez, Scott A. Armstrong, and A. Thomas Look

Normal lymphoid precursors undergo somatic recombination at their immunoglobulin *(Ig)* or T- cell receptor *(TCR)* gene loci,[1] and the successful completion of V(D)J recombination, with the resultant formation of a functional Ig or TCR, is required for the survival of lymphocyte precursors. Positive and negative selection steps ensure that only lymphocytes with Ig or TCRs that function appropriately within the context of an individual's immune microenvironment are allowed to proceed through the proliferation and differentiation steps required for the development of mature lymphocytes. This developmental process generates a repertoire of lymphocytes with unique variations in the antigen-recognition portions of the *Ig* or *TCR* genes, which form the foundation of a fully competent adaptive immune system that can recognize a countless variety of foreign antigens.

The acquisition of somatic genetic alterations involving oncogenes or tumor suppressors can lead to the dysregulated proliferation and clonal expansion of lymphoid precursors that are characteristic of acute lymphoblastic leukemia (ALL). Many genes that are critical to leukemogenesis have been identified through the cloning and characterization of genetic alterations induced by recurrent chromosomal translocations.[2-5] Additionally, a number of translocations have prognostic significance and are used in modern ALL treatment protocols to adjust the intensity of therapy. In many cases, the malignant transformation of lymphoid cells is the result of altered expression of transcription factors that play critical roles in normal B- and T-cell development, although it may also involve the aberrant expression of otherwise quiescent genes. More recent evidence has implicated members of signal transduction pathways in leukemogenesis.[6-8] Although the incidence of specific genetic alterations in ALL varies according to patient age, evidence is accumulating that the pathogenesis underlying malignant transformation in similar genetic alterations is similar across age groups.[9,10]

CLONAL ORIGIN OF LEUKEMIC LYMPHOID CELLS

Human ALL arises from a single progenitor cell that has acquired somatic genetic changes, which lead to dysregulated proliferation and differentiation arrest. The clonal origin of leukemia was first suggested by the identification of the Philadelphia chromosome in chronic myeloid leukemia (CML).[11] Subsequently, numerous lines of evidence have provided additional support for this theory, which is now generally accepted. Uniform structural and numerical chromosomal abnormalities are frequently demonstrated in all leukemic lymphoblasts from an individual patient. Identical rearrangements of *Ig* or *TCR* genes, which are somatic in origin, have been demonstrated in ALL cell populations.[2,12] Additionally, identical patterns of X-chromosome inactivation have been demonstrated within all cells of individual patients with ALL by allelic analysis of the glucose-6-phosphate dehydrogenase gene on the X chromosome.[13] Because X-inactivation occurs in early embryogenesis before somatically acquired mutations begin to promote the transformed phenotype, this is particularly strong evidence for the clonal origin of leukemia. In addition, the methylation patterns of restriction fragment length polymorphisms in X-linked genes, as detected by Southern blot analysis, have been used to show that even rare ALL cases with two completely different cytogenetic clones probably arise by clonal evolution from a single transformed progenitor.[14]

LINEAGE-SPECIFIC FEATURES OF LEUKEMIC LYMPHOBLASTS

An important advance in the understanding and treatment of ALL was the realization that malignant lymphoblasts share many of the features of normal lymphoid progenitors.[15-17] Thus, ALL cells rearrange their *Ig* and *TCR* genes and express components of antigen receptor molecules and other differentiation-linked cell-surface glycoproteins in ways that correspond to features of developing normal B and T lymphocytes. In many cases, leukemic cells appear to represent the clonal expansion of a lymphoid progenitor that has arrested its development at an early stage of B- or T-cell differentiation.[18] Furthermore, research continues with the goal of defining stem cell populations in lymphoblastic leukemia, such as those that have been identified in acute myeloid leukemia (AML).[19] However, with better understanding of the normal patterns of antigen-independent lymphoid cell development, it has become clear that leukemic lymphoblasts can show asynchronous gene expression with subtle variations in phenotype.[20] Hence, it should not be surprising that in some cases of ALL, the blast cell phenotypes differ from those of normal lymphocyte progenitors, which is likely a result of aberrant regulation of gene expression. Still, the general concept that leukemic cells should be classified according to their "normal" developmental stage remains an important one, providing a basis for the study of immunophenotype-specific genetic changes.

B-Cell Acute Lymphoblastic Leukemia

The diagnosis of mature B-cell ALL is based on the detection of surface Ig on leukemic blasts. This rare phenotype accounts for only 2% to 3% of ALL cases, and the lymphoblasts generally have distinctive morphology, with deeply basophilic cytoplasm containing prominent vacuoles; this morphologic pattern is designated L3 in the French-American-British (FAB) system.[21-23] Prominent clinical features include concomitant extramedullary lymphomatous masses in the abdomen or head and neck, frequent involvement of the central nervous system (CNS) and cranial nerves, and tumor lysis syndrome, often complicated by acute renal failure from uric acid nephropathy.

Acute B-cell leukemia appears to be a disseminated form of Burkitt lymphoma because these conditions share common cytogenetic, molecular genetic, immunologic, cytologic, and clinical features.[24] Acute B-cell leukemia does not respond well to chemotherapy traditionally used for childhood ALL. However, good outcomes have been obtained with treatments designed for Burkitt lymphoma, which involve relatively brief but intensive regimens that emphasize cyclophosphamide and the rapid rotation of antimetabolites in high dosages.[25-29] Thus, B-cell leukemia is the first form of ALL to be

recognized as a distinct clinical entity based on immunophenotypic and cytogenetic features and the first to be treated by separate protocols designed specifically for the leukemia's unique features.

B-Precursor Acute Lymphoblastic Leukemia

Approximately 80% of ALL patients have lymphoblasts with phenotypes corresponding to those of B-cell progenitors.[23,30] These cases can be identified on the basis of cell surface expression of CD19 and at least one other recognized B lineage–associated antigen: CD20, CD24, CD22, CD21, or CD79[23,30]; most B-lineage ALL cases also express CD10 (common ALL antigen [CALLA]). The lymphoblasts may also express nuclear terminal deoxynucleotidyl transferase (TdT) or CD34. About one-fourth of B-progenitor ALL cases express cytoplasmic Ig μ heavy-chain proteins and are designated pre–B-cell ALL. Pre-B cases were originally shown to have a worse long-term response to therapy compared with early pre-B cases, an observation that was later attributed to the presence of the t(1;19) translocation that forms the *E2A–PBX1* fusion gene in about one-fourth of the pre-B cases.[31] However, with the introduction of more intensive, risk-adjusted treatment regimens, the prognosis for patients with t(1;19)+ ALL has improved significantly.[32,33]

DNA rearrangement of *Ig* genes occurs before heavy-chain gene expression in B-cell development, providing a genetic marker of B-lymphocyte ontogeny. Korsmeyer and coworkers[34,35] pioneered the use of heavy- and light-chain gene rearrangements to support an early B-lineage origin of most ALL blasts. This work was extended to establish synchrony between *Ig* gene rearrangements and the expression of B lineage–restricted cell surface antigens. However, *Ig* heavy-chain gene rearrangements have also been documented in about 15% of T-cell ALL cases and a similar percentage of AML cases.[36-38] Thus, caution must be exercised when assigning cell lineage on the basis of studies of *Ig* gene rearrangement.

The identification of specific immunophenotypic, genetic, and clinical features that predict response to therapy in patients with B-lineage ALL and the incorporation of these predictors into clinical decision making are now widespread in modern ALL treatment protocols. This ability to predict outcome in these patients has been closely tied to the remarkable improvements in therapy for children with this disease, which 50 years ago was universally fatal. However, many subgroups of pediatric and adult patients face a much poorer prognosis, and much progress remains to be made.

T-Cell Acute Lymphoblastic Leukemia

Leukemias of T-cell precursors can be identified and classified according to the sequence of expression of T-cell–associated surface antigens during normal thymocyte ontogeny.[39,40] In this tightly regulated process, the earliest T-cell precursors are characterized by the lack of expression of CD4 and CD8 surface markers. These double-negative (DN) thymocytes proceed through a series of differentiation stages (DN1-DN4 in mice; pro-T to pre-T in humans) during which the cells lose CD34 expression, gain CD1a expression, and the *TCR* genes *TCR-δ, TCR-γ,* and *TCR-β* become rearranged. The successful rearrangement of *TCR-β* drives the production of immature single-positive cells (ISPs) with a surface $CD4^+$, $CD8^-$, $sCD3^-$ phenotype ($CD4^-$ $CD8^+$ $sCD3^-$ in mice). These cells then differentiate into early double-positive ($CD4^+$, $CD8^+$) cells, at which point the *TCR-α* gene rearrangement occurs. Subsequently, these double-positive progenitors differentiate into late cortical thymocytes showing a loss of CD1 and a gain of surface CD3 expression. This thymic T-cell developmental process ends when mature $CD4^+$ or $CD8^+$ single-positive cells emerge from the thymus,[40,41] although further T-cell differentiation occurs in the periphery upon antigen presentation. Numerous investigators, using a battery of monoclonal antibodies specific for T-cell surface glycoproteins, have confirmed the close relationship between the recognizable patterns of surface antigen expression on leukemic T cells and the normal stages of thymocyte development.[42-45]

Lymphoblasts with a T-cell phenotype comprise approximately 15% of cases of ALL. These are often associated with distinctive clinical features that include high circulating leukocyte counts, a male predominance, CNS involvement, and a radiographically evident thymic mass in many cases at presentation. Historically, patients with T-cell ALL had an adverse prognosis compared with patients with B-lineage ALL, but this gap has narrowed with the intensification of therapy for these patients.[46-48] In marked contrast to B-precursor ALL, in which the availability of a wide range of clinical and genetic prognostic markers has allowed the development of treatment protocols tailored to an individual patient's risk of relapse, robust pretreatment prognostic markers had been lacking in T-ALL[49] until the recent identification of the early T-cell progenitor subtype of T-ALL.

Early T-Cell Progenitor Acute Lymphoblastic Leukemia

Recent work has identified a very high-risk subset of T-ALL cases characterized by differentiation arrest at the earliest identifiable stages of T-cell development, which are defined either by absence of biallelic TCRγ deletion (ABD), indicating differentiation arrest before TCR gene rearrangement, or by expression of a characteristic "early T-cell precursor" (ETP) phenotype.[50,51] These cases comprise 8% to 15% of pediatric T-ALL but appear to comprise a much higher fraction of T-ALL in adults,[52] thus providing one possible explanation for the significantly inferior outcomes of adults versus children with T-ALL. ABD/ETP T-ALL cases have recently been shown to harbor characteristic genetic alterations that include PTEN deletions and activating mutations of RAS, IL-7R, and FLT3, thus implicating these kinases, and the signal transduction pathways they regulate, as novel therapeutic targets in high-risk T-ALL.[50,52,53] Moreover, ETP T-ALL patients also harbor oncogenic alterations that are characteristic of AML or myelodysplastic syndrome (MDS), including *DNMT3A, IDH1/2,* and *EZH2* mutations,[52,53] suggesting that the cell of origin of ABD/ETP T-ALL may be a multipotent hematopoietic stem or progenitor cell rather than a committed T-cell progenitor. Indeed, approximately 20% of relapses in T-ALL patients with biallelic TCRγ rearrangements at diagnosis are characterized by absence of biallelic TCRγ deletion (ABD) at relapse.[50] It is implausible that a cell with a biallelic deletion of genomic DNA would reacquire the deleted sequences; thus, these data further support the hypothesis that, at least in some cases of high-risk T-ALL, the transformed leukemia-initiating clone is an immature progenitor characterized by differentiation arrest at an earlier stage than that of the bulk lymphoblast population at the time of T-ALL diagnosis.

Mixed-Lineage Leukemia

Acute mixed-lineage leukemias are defined by blast cells that coexpress markers of both the lymphoid and myeloid lineages. Two distinct forms of these leukemias are recognized: those with lymphoid morphology that coexpress myeloid-associated antigen[54,55] and those with myeloid morphology and reactivity to myeloperoxidase staining that coexpress cell-surface antigens normally restricted to lymphoid cells. The origin of mixed-lineage leukemias has not been established. One possibility is malignant transformation of pluripotent hematopoietic stem or progenitor cells that retain the ability to differentiate in both the myeloid and lymphoid lineages; another is immortalization of rare progenitor cells that normally coexpress features of both lineages; and a third is aberrant gene expression caused by specific genetic alterations.[56] There was initially considerable controversy over whether patients with lymphoid leukemia with expression of one or more myeloid cell surface antigens (e.g., CD13, CD33, or CD14) had an adverse prognosis. However, more recent data suggest that the coexpression of myeloid antigens in ALL does not carry an adverse prognosis in the setting of contemporary treatment regiments.[57-59] The

expression of lymphoid markers in predominantly myeloid leukemias is relatively rare, and although some studies reported an adverse effect of T-lymphoid markers on outcomes,[60] more recent analyses did not demonstrate a significant prognostic value to lymphoid antigen expression in AML.[61]

GENETIC BASIS OF LYMPHOID LEUKEMIA

Multiple acquired genetic abnormalities are responsible for the aberrant proliferation and differentiation arrest characteristic of ALL. These include chromosomal rearrangements detectable by conventional cytogenetics, as well as lesions that are evident only by molecular analysis. The ability to identify these changes and the discovery that many of these can be used to predict response to therapy have led to risk-adapted therapy for patients with ALL. It is worth noting that the vast majority of patients with leukemia have normal constitutional karyotypes, indicating that the genetic abnormalities in ALL lymphoblasts are usually acquired somatically and thus are restricted to the malignant clone.

Chromosomal translocations are found in 75% of ALL patients (Fig. 63-1).[22,62] They can be broadly classified as recurrent lineage-restricted abnormalities, which account for approximately two-thirds of the translocations in ALL, or as "random" translocations, which

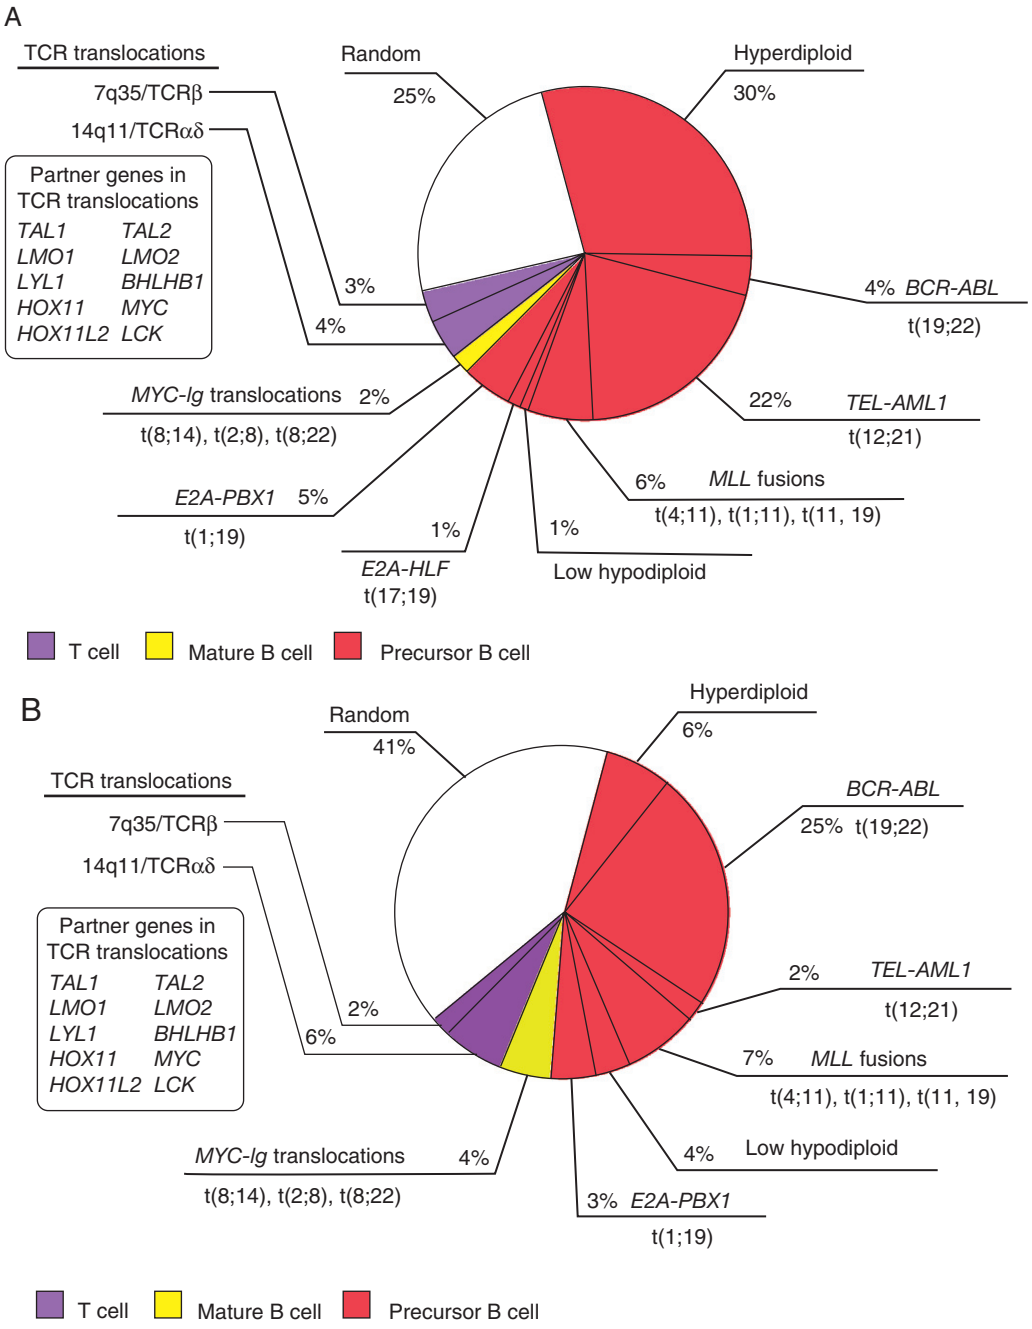

Figure 63-1 FREQUENCY OF THE MAJOR CHROMOSOMAL TRANSLOCATIONS IN PEDIATRIC (**A**) AND ADULT (**B**) ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). The genes affected by chromosomal translocation are shown in *bold*. T-cell receptor (TCR) translocations in T-ALL can activate a number of different proto-oncogenes as shown in the *insert,* including *TAL1, LMO1/2, HOX11, HOX11L2,* and *MYC*.

have been identified only in single or very small numbers of cases. The characterization of genes that span the breakpoints of recurrent translocations has allowed the identification of genes that play critical roles in leukemogenesis.[3-5]

Central Role of Transcription Factors

Molecular studies on recurrent chromosomal translocations in ALL have demonstrated a central role for the aberrant expression of transcription factors in the pathobiology of leukemia (Table 63-1). The dysregulated expression of these transcription factors, which are often functionally normal, leads to abnormal proliferation and differentiation arrest of leukemic lymphoid and myeloid progenitors.[3-5] Conserved amino acid sequence motifs within the sequence-specific DNA binding domains of these nuclear trans-activating proteins allow them to be grouped into families that, in many cases, appear to be involved in similar regulatory processes. Thus, the transcription factor genes in Table 63-1 are grouped according to shared structural features of their DNA-binding domains: basic region helix–loop–helix (bHLH), cysteine-rich (LIM), homeodomain (HOX), basic region-leucine zipper (bZIP), zinc-finger, A-T hook minor groove, ETS-like, or runt homology. Another important association is the lineage restriction of transcription factor genes affected by specific chromosomal translocations, suggesting that the proteins they encode disrupt the differentiation of specific lymphoid progenitors. This interpretation implicates a central role for transcription factors in the initiation of leukemia and suggests that the normal developmental programs of progenitor cells of different lineages are controlled by different regulatory programs.

Rabbitts[63] has aptly described a key group of regulatory transcription factors as the products of "master genes." In his model, the nuclear proteins encoded by these genes act positively to upregulate critical target genes or negatively to interfere with normal regulatory pathways. The net effect is disruption of gene regulatory cascades that control and coordinate the expression of large numbers of proteins required for completion of lymphoid cell differentiation programs. Disruption of transcription factors in leukemic blasts occurs by at least two distinct mechanisms: the dysregulated expression of intact genes and the creation of chimeric transcription factors.

Developmental Biology of Oncogenic Transcription Factors

A surprising connection has emerged from studies of oncogenic transcription factors and the developmental proteins regulating segmentation in *Drosophila* because the DNA-binding domains of these proteins often show striking homology. The proteins participating in leukemogenesis interfere with a highly regulated network of hematopoietic transcription factors, leading to arrested cell development at stages corresponding to those of early lymphoid or myeloid progenitors. Recent evidence implicating the major *HOX* genes in the control of hematopoiesis as well as embryogenesis, together with the established roles of *Drosophila* segmentation genes in controlling *HOM-C* gene expression, suggests that the *HOX* loci may serve as proximal targets of a wide spectrum of hybrid and dysregulated transcription factors in the acute leukemias.[5] In this model, the oncogenic transcription factors inappropriately activate or suppress the expression of *HOX* genes, which in turn regulate gene programs with pleiotropic effects on normal hematopoietic cell development.

The mechanisms that lead to the activation of oncogenic transcription factors in ALL tend to vary according to the ALL subtype. In mature B-cell ALL and in T-cell ALL, genetic lesions that lead to the aberrant expression of structurally intact genes predominate, but the chromosomal translocations that often occur in B-precursor ALL generally lead to the formation of chimeric proteins, which produced as a result of the translocation-induced fusion of the coding sequence of two genes.

Table 63-1 Transcription Genes Affected by Chromosomal Breakpoints in the Acute Lymphoblastic Leukemias

Family*	Translocation	Affected Gene	Disease
Basic helix-loop-helix (bHLH) proteins	t(8;14)(q24;q32)	*MYC*	Burkitt lymphoma and
	t(2;8)(p12;q24)	*MYC*	B-cell ALL
	t(8;22)(q24;q11)	*MYC*	T-cell ALL
	t(8;14)(q24;q11)	*MYC*	T-cell ALL
	t(7;19)(q35;p13)	*LYL1*	T-cell ALL
	t(1;14)(p32;q11)	*TAL1*	T-cell ALL
	t(7;9)(q35;q34)	*TAL2*	T-cell ALL
	t(14;21)(q11.2;q22)	*BHLHB1*	
Cysteine-rich (LIM) proteins	t(11;14)(p15;q11)	*LMO1*	T-cell ALL
	t(11;14)(p13;q11)	*LMO2*	T-cell ALL

Dysregulated Expression of Structurally Intact Genes

Activation of *MYC* in B-Cell Acute Lymphoblastic Leukemia

The vast majority of cases of mature B-cell ALL and Burkitt lymphoma are characterized by a translocation that places one allele of *MYC* from chromosome 8 under the control of the regulatory elements of an *Ig* gene, either the heavy-chain gene on chromosome 14q32 or the κ or λ light-chain genes on chromosomes 2 and 22. This leads to the aberrant expression of *MYC,* a prototypical basic helix–loop–helix oncogenic transcription factor.[64-72] In the predominant t(8;14) translocation, the involved *MYC* locus is translocated into the heavy-chain gene on chromosome 14 adjacent to the coding sequences of the *Ig* constant region.[64-66] The coding sequences of the *Ig* variable region generally are reciprocally translocated to the distal tip of chromosome 8. In variant translocations, the *MYC* gene remains on chromosome 8, and portions of the respective light-chain genes are translocated to that chromosome downstream of the *MYC* locus.[67-71]

Although the *MYC* coding region is not structurally altered by translocation in most cases of B-cell ALL or Burkitt lymphoma, point mutations in the N-terminal phosphorylation domain of *MYC* commonly arise in these tumors at codons 58 or 62.[73-75] These codons are phosphorylation sites involved in the regulation of the activation and degradation of the protein,[76] and these mutations lead not only to the aberrant stabilization of MYC protein[77-79] but also inhibit the ability of *MYC* to activate the proapoptotic *BIM* gene while its ability to stimulate proliferation remains intact.[80]

The mechanisms by which *MYC* exerts its potent growth-promoting effects are complex and only partially understood. *MYC* is estimated to regulate the expression of 15% of the genome[81] and leads to the transcriptional activation of a large number of genes involved in cell division, growth, metabolism, adhesion, and motility.[82] It also leads to the transcriptional repression of many other genes, such as the cell cycle inhibitors p27 and p21. *MYC* exerts its transcriptional activity via the formation of heterodimers with its DNA-binding partner protein MAX–MYC–MAX heterodimers bind to canonical hexameric E-box DNA sequences (5′-CACGTG-3′) where they activate transcription.[83] MAX can also heterodimerize with other bHLHZip proteins, including MAD,[84] MXI-1 (MAD2),[85] and MNT.[86] Whereas transcriptional activation by MYC–MAX complexes promotes proliferation, binding by MAD–MAX and other MAX heterodimers produces opposite effects; for example, MAD inhibits MYC function both by competing with MYC for binding to MAX and by directly inhibiting transcription. Moreover, in addition to its well-established role as a transcriptional regulator, MYC is also an important regulator of microRNA expression and ribosome biogenesis,[87-90] thus implicating additional post-transcriptional regulation of protein expression through which MYC exerts its potent biologic effects.

BHLH, LIM, and *HOX* Genes in T-Cell Acute Lymphoblastic Leukemia

In leukemias with a T-cell phenotype, chromosomal breakpoints consistently involve the *TCR* enhancer (7q34) or the *TCRA/D* enhancer (14q11), both of which are highly active in committed T-cell progenitors and can cause dysregulated expression of transcription factor genes located at the breakpoint on the reciprocal chromosome involved in these phenotype-specific rearrangements.[91] The affected transcription factors include (2) genes encoding bHLH family members, such as *TAL1,*[92,93] *TAL2,*[94] *LYL1,*[95] *MYC,*[96-98] and BHLHB1[99]; (2) LIM-only domain *(LMO)* genes, such as *LMO1* and *LMO2*[100]; and (3) the orphan homeobox genes *HOX11* and *HOL11L1.*[37,101-106] The observation that T-ALL oncogenes act as master transcriptional regulators during the embryologic development of specific organ systems suggests that their aberrant expression in T-cell precursors may contribute to the onset of leukemia by disrupting the mechanisms that control cell proliferation, differentiation, and survival during the discrete steps of normal T-cell development. Gene expression profiling and mutational analyses have shown that cases of T-ALL can be separated into five subtypes based on the pattern of multistep genetic abnormalities that occur (Fig. 63-2).

The best characterized of the oncogenic transcription factors involved in T-ALL is *TAL1* (also known as *SCL*), which is altered by the t(1;14) or by site-specific deletions in approximately one-fourth of childhood T-ALL cases.[107-112] *TAL1* is aberrantly expressed in the leukemic cells of 60% of children and 45% of adults with T-ALL, and its expression is required for maintenance of the leukemic phenotype in human cell culture studies.[113] TAL1 acts as a master regulatory protein during early hematopoietic development and is required for the

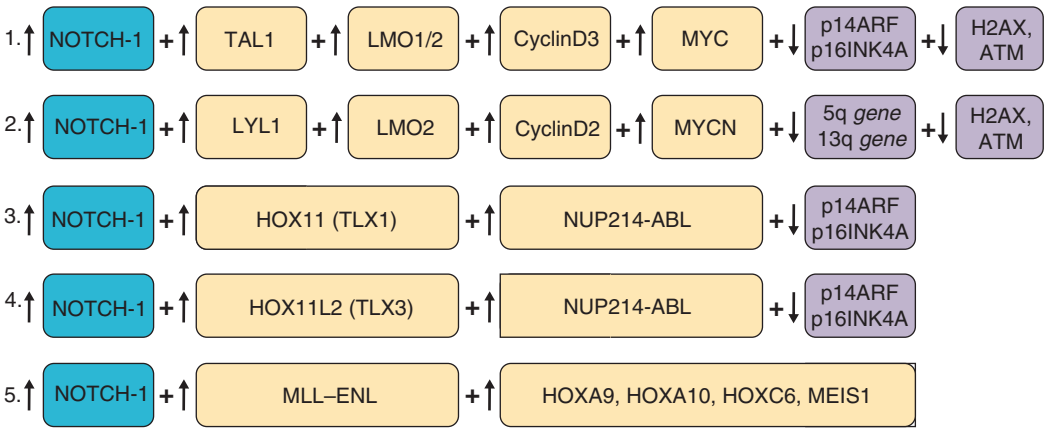

Figure 63-2 MULTISTEP ONCOGENIC PATHWAYS IN T-CELL ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). Gene expression profiling and mutation analyses have revealed that five different multistep molecular pathways can lead to the malignant transformation of developing thymocytes. *NOTCH1* mutations are seen in samples from all five T-ALL subtypes. *HOX11, HOX11L2,* and *TAL1*-overexpressing cases show high levels of *MYC* expression and share the loss of the tumor suppressor genes *p16/INK4A* and *p14/ARF* on chromosome 9p. *HOX11* and *HOX11L2* are often associated with a novel *NUP214-ABL* episomal fusion gene, which may render these T-ALLs sensitive to imatinib. *LYL1+* cases show high levels of expression of *N-MYC* and frequently have deletions affecting as yet unidentified loci on chromosomal arms 5q and 13q. Finally, *MLL–ENL+* cases have a clearly distinct gene expression profile characterized by low expression of *MYC* and other genes involved in cell growth and proliferation but high expression of *HOXA9, HOXA10,* and *HOXC6* in concert with the *HOX* gene regulator *MEIS1*. *(Adapted from Armstrong SA, Look AT: Molecular genetics of acute lymphoblastic leukemia.* J Clin Oncol *23:6306, 2005, with permission.)*

generation of all blood cell lineages.[114,115] However, it does not seem to be required for the generation and function of hematopoietic stem cells (HSCs) during adult hematopoiesis.[116] This class II bHLH transcription factor binds to DNA by forming heterodimers with class I bHLH factors such as E2A.[117] Although TAL1 binding to promoter sites that are normally occupied by TAL1, E2A or HEB can lead to either repression or activation of transcription.[113] TAL1 appears to exert its leukemogenic effects largely via the inhibition of E2A activity.[118] The observation that loss of E2A function induces T-cell leukemias in mice[119,120] and that the DNA-binding domain of TAL1 is dispensable for transformation in transgenic mouse models[121] gives additional support to the notion that TAL1-mediated inhibition of E2A plays a central role in its pathogenesis in T-ALL.

The LIM-only domain genes, *LMO1/RBTN1/TTG1* and *LMO2/RBTN2/TTG2,*[100,122,123] encode proteins that possess duplicated cysteine-rich LIM domains involved in protein–protein interactions. LMO2 interacts with TAL1 in erythroid cells and in T-cell leukemias.[124-126] Moreover, homozygous disruption of *LMO2* in mice causes the same phenotype as described earlier for *TAL1* knock-outs, indicating that a multiprotein complex is required for normal hematopoietic development that involves LMO2, TAL1, and other proteins such as GATA1.[127-130] In addition, overexpression of *LMO1* or *LMO2* in thymocytes of transgenic mice leads to T-cell lymphomas, recapitulating human T-cell tumors,[131-135] and accelerates the onset of leukemias in *TAL1* transgenic mice lines.[126]

The homeodomain gene *HOX11* (also known as *TLX1*), located on chromosome 10, band 24, is one of the more interesting proteins activated by translocation into the vicinity of the *TCR* loci.[37,102,104-106] *HOX11* is the founding member of a family of *HOX* genes that includes *HOX11L1* and *HOX11L2*[106] and whose family members are characterized by the presence of a threonine in the third helix of the homeodomain, which confers specific DNA binding properties. *HOX11* was originally isolated from the recurrent t(10;14)(q24;q11) in T-ALL[37,102,104,105] and is aberrantly expressed in 5% of pediatric and up to 30% of adult T-ALL patients.[101,136,137] The relatively low frequency translocations involving the *HOX11* locus on 10q24, 2% to 5% in childhood T-ALL[105] and 14% in adult cases,[138] suggests that alternative mechanisms leading to *HOX11* overexpression account for the activation of this transcription factor oncogene in a significant fraction of T-ALL cases.

Similar to other *HOX* genes, *HOX11* plays an important role in embryonic development, and functions as a master transcriptional regulator necessary for the genesis of the spleen.[139,140] In the mouse embryo, *Hox11* expression can be detected in the branchial arches, restricted areas of the hindbrain, and the splenic primordium,[141,142] where it is required for the survival of early splenic progenitors.[140] The *HOX11* oncogenic transcription factor is associated with T-cell leukemogenesis at the early cortical thymocyte stage and relies on specific homeodomain-DNA interactions for its leukemogenic effects.[143] Additionally, *HOX11* directly interacts with the catalytic subunits of the serine–threonine phosphatases PP2A and PPA, which mediates disruption of the G2/M cell cycle checkpoint.[144]

A second *HOX11* family member, *HOX11L2,* has also been implicated in the pathogenesis of human T-ALL through characterization of the t(5;14)(q35;q32), a cryptic chromosomal rearrangement detectable only by fluorescence in situ hybridization or by chromosome painting techniques.[103] This translocation leads to the ectopic expression of *HOX11L2,* possibly by bringing it under the influence of regulatory elements in the *CTIP2/BCL11B* gene, which is highly expressed during T-lymphoid differentiation. In contrast to the predominance of *HOX11* expression in adult T-ALL cases, both the t(5;14) and expression of *HOX11L2* can be detected in 20% to 25% of children but in only 5% of adults with T-ALL.[101,137,145-147] The role of HOX11L2 as a master transcriptional regulator upstream of important pathways involved in cell fate determination is supported by its importance during embryonic development.[148] In mice, *Hox11l2* expression is essential for normal development of the ventral medullary respiratory center.[148] Mice deficient in this protein die soon after birth from respiratory failure that resembles congenital central hypoventilation syndrome in humans.

HOX11 and HOX11L2 are closely related in structure and have a high degree of homology at the amino acid level, especially in the homeobox domain, where their sequences differ by only three amino acids. The high level of structural homology in their DNA-binding domains supports the hypothesis that HOX11 and HOX11L2 may induce T-ALL through regulation of the same transcriptional targets. *HOX11* expression has recently been shown to induce T-ALL in mice and to disrupt the mitotic checkpoint via inhibition of *CHK1,* thus accounting for the association of *HOX11/HOX11L2* overexpression with aneuploidy, which is otherwise rare in human T-ALL.[149]

Recently, the analysis of gene expression profiling using oligonucleotide microarrays has shown that the expression of different transcription factor oncogenes such as *TAL1, LYL1, HOX11,* and *HOX11L2* is associated with distinct gene expression profiles. These unique signatures resemble those of thymocytes blocked at discrete stages of T-cell development (Fig. 63-3),[17] suggesting that transcription factor oncogenes contribute to the pathogenesis of T-ALL by interfering with critical regulatory networks that control cell proliferation, survival, and differentiation during T-cell development.[17] Based on the patterns of aberrant gene expression, human cases of T-ALL can be classified into five different subtypes (see Fig. 63-2).

HOXA Cluster Translocations in T-Cell Acute Lymphoblastic Leukemia

A recurrent inversion on chromosome 7 that places the *HOXA* cluster in the vicinity of the TCR β gene regulatory elements and that leads to activation of the entire *HOXA* cluster was recently discovered in approximately 5% of cases of T-ALL.[150,151] Many of these patients also carried cooperating oncogenic lesions consisting of *NOTCH1* gene mutations and deletions of 9p21.[152] This new translocation that directly activates *HOXA* gene expression provides additional evidence for the role of aberrant *HOXA* activation in leukemogenesis and in the pathogenesis of *MLL- and CALM-AF10*–rearranged leukemias.

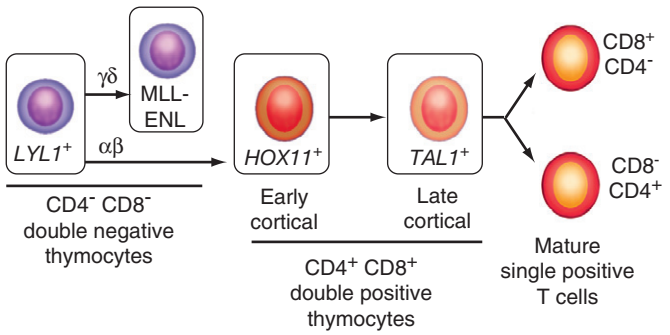

Figure 63-3 THYMOCYTE DEVELOPMENT IS A TIGHTLY REGULATED PROCESS IN WHICH PROGENITOR CELLS UNDERGO SEQUENTIAL STAGES OF DIFFERENTIATION, PROLIFERATION, LINEAGE COMMITMENT, AND SELECTION THAT RESULT IN THE PRODUCTION OF FUNCTIONALLY COMPETENT MATURE T CELLS. Microarray gene expression profiling shows that T-ALL lymphoblasts expressing high levels of the LYL1 transcription factor oncogene undergo an early arrest at the double-negative thymocyte ($CD4^-$, $CD8^-$) stage of development. In T-ALL cases with aberrant expression of HOX11, the leukemic cells show a developmental arrest at the double-positive ($CD4^+$, $CD8^+$) early cortical stage of thymocyte differentiation, but those with aberrant expression of TAL1 are arrested at the double positive late cortical stage. T-ALL cells with expression of the *MLL-ENL* fusion gene are characterized by an early arrest of differentiation with a gene expression signature that indicates commitment to the γ-delta lineage. *(Adapted from Ferrando AA, Neuberg DS, Staunton J, et al: Gene expression signatures define novel oncogenic pathways in T cell acute lymphoblastic leukemia.* Cancer Cell *1:75, 2002, and Ferrando AA, Look AT: Gene expression profiling in T-cell acute lymphoblastic leukemia.* Semin Hematol *40:274, 2003, with permission.)*

Other Genes Activated by Translocation

Transcription factors are not the only genes activated by translocation to the sites of the *Ig* or *TCR* genes. In cases of B-precursor ALL carrying the t(5;14), for example, the *IL-3* gene is activated by juxtaposition with the *Ig* heavy-chain locus.[153,154] Similarly, relocation to the *TCRB* locus activates expression of the *LCK* tyrosine kinase genes in T-ALL cases with the t(1;7).[155-157]

Chimeric Transcription Factor Genes

Formation of chimeric proteins whose functional domains come from two normally separate genes represents a second mechanism of aberrant transcription factor activation, which is more prevalent in B-precursor ALL. These chromosomal translocations result in the production of a chimeric protein by fusing the DNA-binding, dimerization, and trans-activation regions of discrete genes. This process is facilitated by the molecular structure of transcription factors in which discrete coding regions of each gene encode particular functional domains; this molecular structure likely arose for evolutionary reasons.

E2A-PBX1 Fusion Genes in Pre-B Cell Acute Lymphoblastic Leukemia

A well-known example of a chimeric transcription factor with oncogenic potential is the *E2A-PBX1* rearrangement, which results from the t(1;19)(q23;p13) chromosomal translocation present in about 5% of all B-lineage ALLs and in 25% of cases with a pre-B (cytoplasmic Ig-positive) phenotype.[32,91,158] This translocation fuses the transactivation domain of the *E2A* transcription factor on chromosome 19 to a homeobox gene *(PBX1)* on chromosome 1, leading to the expression of several forms of hybrid E2A-PBX1 oncoproteins.[159-161] *PBX1* is related to the *Drosophila exd* gene, a homeobox gene that plays a role in lymphocyte development.[162,163] The hybrid proteins resulting from the t(1;19) retain the amino-terminal trans-activation domains of E2A (AD1 and AD2) but not the bHLH DNA-binding/protein interaction domain.[160,161,164] The bHLH domain is replaced by the homeobox DNA-binding domain of PBX1, enabling the fusion protein to function as a chimeric transcription factor.[165-167]

The transforming potential of *E2A–PBX1* was first demonstrated by the rapid induction of AML in lethally irradiated mice repopulated with bone marrow stem cells that had been infected with recombinant retroviruses containing *E2A–PBX1* genes.[168] The fusion has also been shown to transform NIH-3T3 fibroblasts and induce T-cell lymphomas in transgenic mice.[169,170] Additional studies have shown that deletion of one of the E2A activation domains diminishes its transforming activity, but deletion of the PBX1 homeodomain has no effect.[170,171] However, the homeodomain and flanking sequences are required for interactions with other HOX proteins and for optimal binding of E2A–PBX1 to specific DNA sequences.[172-176] It thus appears that complex interactions between E2A–PBX1 and other HOX proteins target the fusion protein to specific target genes whose activation is critical to lymphoid cell transformation. The presence of the *E2A–PBX1* translocation was originally associated with a poor prognosis.[31] However, this translocation no longer imparts an adverse prognosis in the setting of modern risk-adjusted protocols for childhood ALL.[32,177-179]

E2A–HLF Fusion Genes in Early Pre-B Acute Lymphoblastic Leukemia

The t(17;19) is a rare recurrent chromosomal translocation that fuses the amino-terminal transactivation domains of E2A to the C-terminal DNA binding and dimerization domains of HLF,[180,181] which belongs to the PAR subfamily of bZIP transcription factors. Although E2A–HLF can bind DNA either as a homodimer or as a heterodimer with HLF and related proteins, no other PAR proteins are expressed in hematopoietic cells, and the E2A–HLF fusion binds DNA as a homodimer in cells harboring the t(17;19). Similar to E2A–PBX1, E2A–HLF can transform NIH–3T3 fibroblasts, a process that requires the HLF leucine zipper domain and the E2A transactivation domains.[182] E2A–HLF can also induce lymphoid tumors in transgenic mice.[183]

A major consequence of the activation of E2A–HLF in lymphoid precursors is dysregulation of the mechanisms that control programmed cell death in lymphoid progenitors. Expression of a dominant-negative form of E2A–HLF in t(17;19)-carrying cell lines blocks E2A–HLF function and results in apoptosis.[184] In normal pro-B lymphocytes, expression of E2A–HLF reversed IL-3-dependent and p53-induced apoptosis. HLF is the mammalian homologue of the nematode protein ces-2, which regulates the death of specific nerve cells in *Caenorhabditis elegans*.[184-186] Ces-2 is necessary for the death of the sister cells of a specific pair of serotonergic neurons during worm development. Ces-2 induces apoptosis by inhibiting the expression of *ces-1,* a prosurvival gene that normally inhibits programmed cell death by antagonizing the activity of the proapoptotic factor *egl-1*. This pathway, which is highly conserved through evolution, is disrupted by E2A–HLF fusion. Thus, in contrast to the proapoptotic role of ces-2 in the worm via repression of ces-1, E2A–HLF blocks apoptosis by inducing the expression of *SLUG,* a *ces-1* homologue normally responsible for protecting hematopoietic progenitors from DNA-damage–induced apoptosis.[187-190]

The t(17;19) is seen in fewer than 1% of ALL patients, typically occurs in adolescents, and is associated with disseminated intravascular coagulation and hypercalcemia at diagnosis. The t(17;19) seems to impart unfavorable prognosis because each of seven patients whose blasts expressed *E2A–HLF* died of leukemia despite aggressive therapy.[91] It seems likely that resistance to chemotherapy in these cases is mediated by the role of E2A–HLF in driving the expression of *SLUG* and inhibiting apoptosis.[190]

MLL Fusion Genes

Translocations involving chromosome 11 band q23 occur in approximately 80% of infant ALL cases, 5% of AML cases, and 85% of secondary AML cases that occur in patients treated with topoisomerase II inhibitors.[91] The gene bisected by 11q23 translocations is designated *MLL* (also known as *TRX1* or *ALL-1*), which is the human ortholog of the trithorax *Drosophila* gene.[191-194] The trithorax group family of proteins are positive regulators of homeobox gene expression and act antagonistically to the polycomb group of proteins.[195] Wild-type MLL positively regulates *HOX* gene expression and is required for both primitive and definitive hematopoiesis.[196-198] The MLL protein undergoes proteolytic processing by Taspase1, a specialized protease that cleaves the MLL protein into N-terminal (MLL^N) and C-terminal (MLL^C) fragments that remain associated through intramolecular protein–protein interaction domains.[199-201] MLL^N contains several DNA-binding domains, including AT-hook domains that nonspecifically bind the minor groove of DNA, a methyltransferase homology region (CxxC domain) that specifically binds unmethylated DNA, four plant homeodomain zinc fingers with an embedded bromodomain, and a transcriptional repression domain.[195] The C-terminal fragment MLL^C contains a transcriptional activation domain that recruits the histone acetyltransferase cAMP response element-binding protein (CBP) and a SET domain that is responsible for its histone 3 lysine 4 (H3K4) methyltransferase activity.[201] Recent studies have revealed that wild-type MLL is a member of a large multiprotein complex involved in chromatin modification and remodeling, together with histone deacetylases and members of the Swi/Snf chromatin-remodeling complex.[202]

MLL fusion oncogenes result from translocations whose breakpoints cluster between exons 5 and 11 of *MLL,* and the resultant fusion proteins retain the N-terminal region of *MLL,* including the AT-hook and CxxC domains that bind DNA in a sequence-nonspecific manner.[203] By contrast, the C-terminal domains that

mediate the association of wild-type MLL with its endogenous chromatin modification–remodeling complex and its H3K4 methyltransferase activity are invariably lost from oncogenic MLL fusion proteins. Instead, the C-terminus of MLL fusion oncoproteins is provided by one of more than 60 different translocation partners, with common translocations such as the t(4;11), t(9;11), and t(11;19)(q23;p13.3) resulting in the in-frame fusion of *MLL* to *AF4, AF9,* and *ENL,* respectively. The unrelated t(11;19)(q23;p13.1) translocation results in fusion of MLL to ELL, the RNA polymerase II elongation factor.[204,205]

Formal proof that *MLL* fusions play a critical role in the development of leukemias has come from the generation of murine models of *MLL*-induced leukemias. Chimeric mice harboring a *MLL–AF9* fusion gene generated by homologous recombination developed leukemias with a latency of 4 to 12 months.[206] Retroviral transduction of *MLL–ENL, MLL–ELL,* and *MLL–CBP* fusion genes in hematopoietic precursors induces transformation upon transplantation into recipient mice.[207-209] Similar results were recently obtained with a model in which chromosomal translocations involving the *Mll* locus are induced by directed interchromosomal recombination in mice, a strategy that reproduces experimentally the initiating events in the pathogenesis of *MLL*-rearranged leukemias.[210] Interestingly, the introduction of MLL–AF9 into committed granulocyte-macrophage progenitors in the mouse leads to the reactivation of a subset of genes normally expressed only in HSCs and transforms these committed precursors into AML leukemic stem cells by imparting the properties of self-renewal,[211] suggesting that the leukemogenic lesion in MLL-rearranged leukemia might occur in a committed progenitor rather than in a pluripotent HSC.

The analysis of gene expression profiles in *MLL*-rearranged B-lineage leukemias has shown that these tumors have a characteristic gene expression signature that includes the upregulation of several *HOX* genes and the expression of numerous myeloid markers.[212-214] Both early B- and T-cell ALLs with MLL rearrangements showed a characteristic upregulation of specific *HOX* genes, including *HOXA9, HOXA10,* and *HOXC6* and the *HOX* gene regulator *MEIS1*.[212-214] These results, together with the demonstration that *HOXA9* plays important roles in the transformation of hematopoietic precursors by MLL fusion oncogenes in murine leukemia models,[215,216] emphasize the central role of *HOX* gene dysregulation in the pathogenesis of *MLL*-rearranged leukemias. Additionally, as discussed later in this chapter, overexpression or activating mutations of the FLT3 receptor tyrosine kinase are frequent in *MLL*-rearranged leukemias,[212,213,217,218] and a model of the multistep pathogenesis of *MLL*-rearranged ALL is depicted in Fig. 63-4.

Until recently, the precise mechanisms mediating the oncogenic activity of MLL fusion oncoproteins was unclear because MLL translocation partners have little sequence or functional similarity. However, recent work has shown that a number of distinct MLL translocation partners are functionally linked through their association in protein complexes that mediate transcriptional elongation.[219] Oncogenic MLL-fusion proteins associate with at least three such complexes, PAFc, DOT1L, and pTEFb (also known as SEC or AEP). PAFc, the polymerase-associated factor complex, regulates RNA polymerase II and associates with the amino-terminus of both wild-type MLL and MLL fusions.[220] The pTEFb complex (CDK9–cyclin T) phosphorylates RNA polymerase II; interacts with several MLL fusion partners, including ENL, ELL, AF4, and AF5; and co-purifies with several MLL fusion proteins.[221,222] The DOT1L complex consists of DOT1L; a histone H3 lysine 79 (H3K79) methyltransferase; and multiple MLL fusion partners, including AF9, ENL, and AF10.[223-228] Analysis of H3K79 methylation status has revealed increased methylation at genes overexpressed in MLL fusion-driven leukemias, including several direct targets of MLL fusions such as the 5′ HOXA cluster genes and MEIS1.[229-231] Interestingly, whereas the DOT1L methyltransferase is required for transformation of murine

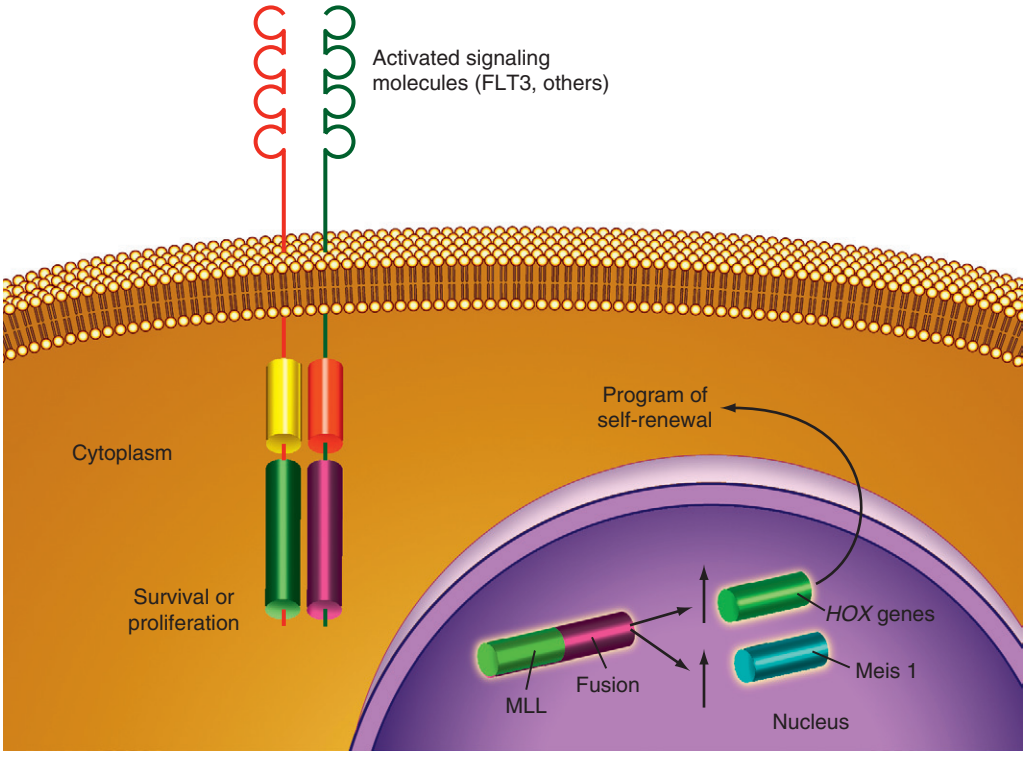

Figure 63-4 MULTISTEP PATHOGENESIS OF MLL-REARRANGED ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). MLL translocations induce self-renewal in hematopoietic progenitors as a first step in leukemogenesis. The presence of FLT3 mutations in MLL-rearranged ALLs support activation of FLT3 or other kinases as cooperating events in this disease. Clinical trials designed to assess the efficacy of FLT3 inhibitors in MLL-rearranged ALL are being developed. *(Adapted from Armstrong SA, Look AT: Molecular genetics of acute lymphoblastic leukemia.* J Clin Oncol *23:6306, 2005, with permission.)*

bone marrow progenitors by MLL fusion oncoproteins, DOT1L plays a less prominent role in normal hematopoiesis, thus suggesting a therapeutic window for therapeutic targeting of DOT1L in MLL-driven leukemias.[227,232-235] Indeed, a small molecule inhibitor of DOT1L has recently been developed and demonstrates promising activity against MLL-positive leukemia cells in vitro and in vivo, with little toxicity in murine models.[236]

The presence of MLL rearrangements is associated with dismal outcomes despite aggressive chemotherapy in most cases of ALL.[23,237-239] Additionally, bone marrow transplantation (BMT) in first remission in these patients is not clearly beneficial and may actually be associated with a decrease in event-free and overall survival compared with chemotherapy alone.[239,240] However, the recent data implicating DOT1L as a promising therapeutic target in MLL-driven leukemias have generated considerable enthusiasm for the development of clinical DOT1L inhibitors for the treatment of MLL-rearranged leukemias.

CALM–AF10 Fusion Gene in T-Cell Acute Lymphoblastic Leukemia

The t(10;11)(p13;q14) detected in approximately 3% to 10% of T-ALL patients and in occasional AML patients and results in the fusion of *CALM,* encoding a protein with high homology to the murine clathrin assembly protein ap3, with *AF10,* a gene identified as an MLL partner in the MLL–AF10 fusion resulting from the t(10;11)(p13;q23).[241] Although the mechanism of action of CALM–AF10 remains incompletely understood, the expression of this fusion transcript has been associated with early arrest in T-cell development and to differentiation into the γ-δlineage in T-ALL.[242] Additionally, recent evidence suggests that aberrant upregulation of *HOX* gene expression appears to be involved in CALM–AF10-mediated leukemogenesis, at least in AML cells that carry this translocation.[243] Interestingly, analysis of a mouse model of CALM–AF10-induced AML suggests that the leukemia stem cell in this model has lymphoid characteristics, and cells from human patients with AML can be identified that have similar characteristics to the disease-propagating cell in this animal model.[244]

TEL–AML1 (ETV6-RUNX1) Fusion Gene in Early Pre-B Acute Lymphoblastic Leukemia

Although most t(12;21) translocations are not detectable by standard cytogenetic analysis, this translocation is detectable by molecular techniques in approximately 25% of childhood B-lineage ALL, which makes this the most common genetic lesion in pediatric ALL.[91] The *TEL–AML1* translocation often arises prenatally and is probably the initiating mutation in ALL, as evidenced by the identification of identical *TEL–AML1* translocations in identical twins with concordant ALL[245] and in retrospectively analyzed neonatal blood specimens of children diagnosed with ALL.[246] However, *TEL–AML1* is insufficient in causing leukemia because the incidence of detectable *TEL–AML1* fusions in the blood of normal newborns is about 100-fold greater than the incidence of leukemia.[247]

The molecular mechanisms mediating *TEL–AML1*-induced leukemogenesis remain poorly understood. This fusion gene encodes a chimeric protein that contains the helix–loop–helix (HLH) domain of TEL fused to nearly all of AML1 (also known as RUNX1 or CBFA2), including both the transactivation domain and the DNA- and protein-binding Runt homology domain. Both of these genes are found in other leukemia-related translocations, and both are essential for normal hematopoiesis. *TEL* was first identified in the t(5;12) in chronic myelomonocytic leukemia, where it is fused to the platelet derived growth factor receptor gene *(PDGFRB),* and is also fused to *ABL, MN1,* and *EVI1* in AML and to *JAK2* in T-ALL.[248] The role of TEL in hematopoiesis has been demonstrated with a conditional mouse model in which the absence of TEL in early development leads to the absence of fetal hematopoiesis. Interestingly, the inactivation of TEL in adult mice leads to the selective loss of HSCs from adult bone marrow, but hematopoiesis is sustained by committed precursors.[249] Most *TEL–AML1* leukemias show loss of the normal *TEL* allele, suggesting that the leukemogenic effect of TEL-AML1 may be mediated in part by loss of function of the *TEL* gene.[250-253]

AML1 is the DNA-binding component of the AML1–CBFß transcription factor complex disrupted by the t(8;21), t(3;21), and inv(16) in AML, making it the most common target of chromosomal translocations in leukemia. AML1 is a transcription factor that has been shown to be required for the expression of several hematopoietic genes involved in myeloid and lymphoid development, including *PU.1* and IL-3, although it can also act as a transcriptional repressor in some settings.[254] Homozygous disruption of the murine *AML1* gene or *CBFB* gene results in the lack of definitive hematopoiesis, indicating that genes regulated by AML1 are essential for normal hematopoietic development.[255,256] Additionally, rare familial mutations in the *AML1* DNA-binding domain lead to the familial platelet disorder and predisposition to myeloid malignancy syndrome.[257] However, the molecular pathways mediating *TEL–AML1*-induced leukemogenesis remain incompletely understood.

The presence of the *TEL–AML1* translocation is associated with an excellent prognosis, with event-free survival rates of approximately 90% in a variety of studies.[91,258,259] However, *TEL–AML1* may not represent an independent predictor of prognosis when age and white blood cell count at the time of diagnosis are taken into account in multivariate analysis.[259] Nevertheless, this translocation identifies a large subset of children with B-precursor ALL who appear to represent good candidates for less intensive therapy. The *TEL–AML1* translocation is associated with lower expression of the *MDR-1* multidrug resistance gene[260] and of genes involved in purine metabolism,[261] which might account for the particular efficacy of these cases to current combination chemotherapy regimens that rely heavily on methotrexate and mercaptopurine, agents that inhibit de novo purine synthesis.

Tyrosine Kinase Genes

BCR–ABL in B-Precursor Acute Lymphoblastic Leukemia

The 22q$^-$ chromosomal marker, often called the Philadelphia (Ph) chromosome, which arises from the t(9;22)(q34;q11), was originally identified in patients with CML, although it is also found in about 4% of childhood cases and 25% of adult cases of ALL,[91] which are almost always of the B-precursor subtype. The t(9;22) generates a *BCR–ABL* fusion gene, consisting of 5′ (upstream) sequences from *BCR* and 3′ (downstream) sequences of ABL. The t(9;22) breakpoints on the distal tip of the long arm of chromosome 9 are scattered over a distance of nearly 200 kb within the first intron of the *ABL* proto-oncogene, upstream of the tyrosine kinase domain.[262-264] The breakpoints in the *BCR* gene on chromosome 22 cluster in two separate regions of that gene, known as the major breakpoint cluster region (M-bcr) or minor breakpoint cluster region (m-bcr). In two-thirds of cases of Ph-positive ALL, the breakpoint in the *BCR* gene occurs in the minor breakpoint cluster region (m-bcr), but in all cases of CML and about one third of cases of ALL, the breaks occur in the major breakpoint cluster region (M-bcr).[265] The fusion transcript more commonly present in ALL (m-bcr) encodes a 190-kd protein (p190), but the transcripts found in CML and some cases of ALL (M-bcr breakpoint) encodes a 210-kd hybrid protein (p210).[266-269] Both types of fusions generate chimeric oncoproteins that are activated as a tyrosine-specific protein kinase, similar to the v-abl protein.[270-272]

The ABL tyrosine kinase is localized both in the nucleus and in the cytoplasm of proliferating cells. It is normally activated by DNA damage downstream of ATM and appears to promote p53-mediated growth arrest.[273-276] Mice deficient in ABL develop a wasting syndrome

and die soon after birth.[277,278] In contrast to the nuclear and cytoplasmic distribution of normal ABL, the BCR–ABL fusion oncoprotein has a cytoplasmic location and shows increased tyrosine kinase activity.[279,280] When expressed in murine hematopoietic precursors, both p190 and p210 transform hematopoietic cells in vitro and induce a syndrome similar to CML in mice.[281-284] Transformation by the BCR–ABL oncoprotein involves activation of the RAS–MAPK (mitogen-activated protein kinase) pathway, PI-3 and JUN kinases, c-CBL and CRKL, JAK–STAT, NFκB (nuclear factor kappa-B), Src, and cyclin D1.[285-292] Among these targets, the RAS, JUN–kinase, and PI-3 kinase pathways are involved in the induction of cell proliferation.[293] The BCR–ABL oncoprotein affects multiple aspects of cell homeostasis, including apoptosis, differentiation, and cell adhesion. An important cellular effect of BCR–ABL is the induction of cellular resistance to DNA damage agents such as cytostatic drugs and irradiation. After DNA damage, BCR–ABL extends the duration of the G2/M cell cycle checkpoint and facilitates DNA repair. It also upregulates the antiapoptotic *BCLXL* gene, contributing to the suppression of apoptotic cell death.[294]

The presence of the Philadelphia chromosome has historically been associated with an extremely poor prognosis in ALL patients despite treatment with intensified chemotherapeutic regimens.[295-297] However, these patients have been shown to have particularly good responses to allogeneic BMT in first remission, whether from matched sibling or from unrelated donors.[298-302] Moreover, the development of imatinib mesylate, a pharmacologic tyrosine kinase inhibitor targeting the BCR–ABL oncoprotein, has opened novel therapeutic opportunities for the management of Ph-positive ALL. The utility of imatinib as a single agent for BCR–ABL ALL is limited by the rapid development of drug resistance.[303,304] However, the combination of imatinib with conventional chemotherapy has led to remarkable improvements in outcome for patients with BCR–ABL ALL, with 3-year survival rates in children with this disease rivaling those obtained with BMT.[305]

Despite its activity, imatinib resistance remains a barrier to further therapeutic improvements in BCR–ABL ALL. Resistance most commonly emerges because of point mutations in the kinase domain of BCR–ABL, and a series of novel BCR–ABL1 kinase inhibitors have been developed that retain activity against many of these mutant oncoproteins.[306-308] Although not all BCR–ABL mutations that confer resistance can be overcome with newer agents, the potential of these newer BCR–ABL inhibitors with broader specificity to further improve outcomes is actively being investigated. Additionally, a novel pathway mediating resistance to BCR–ABL inhibition has recently been uncovered in BCR–ABL ALL lymphoblasts. Upon BCR–ABL inhibition, these cells markedly upregulate expression of the BCL6 transcription factor, a well-known oncogene that is often translocated in diffuse large B-cell lymphomas.[309] BCL6 then blocks activation of the p53 pathway via transcriptional repression of ARF and thus blocks the therapeutic efficacy of monotherapy with imatinib in BCR–ABL ALL cells. Importantly, inhibition of BCL6 activity generically or using a peptide inhibitor of BCL6 demonstrated marked activity in patient-derived BCR–ABL ALL cells grown in immunodeficient mice, highlighting the therapeutic relevance of these findings.[310]

NUP214–ABL1 in T-Cell Acute Lymphoblastic Leukemia

Although the *BCR–ABL1* translocation is rare in T-cell ALL, amplified episomes containing *NUP214–ABL1* fusion genes have recently been described in approximately 6% of children and adults with T-cell ALL.[311] These episomes appear to arise via a mechanism in which the genomic region of chromosome 9q34, which contains both the *NUP214* and *ABL1* genes, is circularized in a manner that leads to the fusion of these two genes. The breakpoint in the *ABL1* gene in all of these cases occurs in intron 1, which is the same breakpoint observed in Philadelphia-positive CML and B-precursor ALL, but the *NUP214* breakpoints are variable. The wild-type *NUP214* protein is a component of the nuclear pore complex and may contribute oligomerization motifs to the *NUP214–ABL1* fusion oncogene. The NUP214-ABL1 fusion protein has constitutively activated ABL1 tyrosine kinase activity, which is inhibited by the BCR–ABL kinase inhibitor imatinib.[311] The therapeutic potential of imatinib or second-generation tyrosine kinase inhibitors for *NUP214–ABL1*-positive T-cell ALL is of considerable interest.

FLT3 in *MLL*-Rearranged Acute Lymphoblastic Leukemia

FLT3 encodes a receptor tyrosine kinase that is highly expressed in early hematopoietic precursors, where it plays important functional roles.[312,313] Multiple studies have shown that activating mutations of *FLT3,* which lead to constitutive receptor tyrosine kinase activity even in the absence of ligand, are common in leukemic myeloblasts in patients with AML but are rare in adults with ALL.[314-316] However, gene expression studies demonstrated high expression of *FLT3* in most cases of ALL that involve MLL gene rearrangements or hyperdiploidy.[212,213,217] Additionally, activating mutations were identified in 18% of infants with MLL-rearranged ALL,[218] in 21% to 24% of hyperdiploid ALL cases,[7,218] and in all three cases of the prothymic CD117/KIT+ subtype of T-cell ALL in adults who were examined.[317]

In the absence of FLT3 ligand, wild-type FLT3 receptors are inactive because of autoinhibition mediated by the juxtamembrane domain of the receptor. Upon binding of FLT3 ligand, normal FLT3 receptors homodimerize, become activated by phosphorylation, and lead to the activation of signal transduction pathways that promote proliferation and cell survival.[318] Activating mutations of *FLT3* found in leukemias occur in two separate regions of the gene. In-frame tandem duplications in the juxtamembrane domain lead to loss of the autoinhibiton mediated by this domain, with subsequent dimerization and receptor activation in the absence of FLT3 ligand.[319] Alternatively, point mutations or insertions in the second tyrosine kinase domain of the FLT3 receptor lead to autophosphorylation and activation of downstream signaling in the absence of FLT3 ligand.[6,316,320] Small molecule inhibitors of the FLT3 kinase lead to apoptosis in AML cell lines in vitro and are currently undergoing phase I and II testing in adults with AML and MDS.[321] These small molecule inhibitors are also active against MLL-rearranged ALL cell lines[217,322] and hold promise as targeted therapies for cases of ALL that rely on aberrant activation of FLT3.

CRLF2 and *JAK2* Mutations in B-Precursor Acute Lymphoblastic Leukemia

The CRLF2 cytokine receptor binds its ligand, thymic stromal lymphopoietin (TSLP), as a heterodimeric complex with the IL-7 receptor subunit (IL-7R). TSLP–CRLF signaling plays physiologic roles during normal B-cell development and in inflammation. Genomic analyses of B-precursor ALL patient samples revealed recurrent deletions within the pseudoautosomal region of Xp22.3/Yp11.3 that result in overexpression of the entire coding region of CRLF2 under control of gene regulatory elements of P2RY8, a purinergic receptor that is expressed at high levels in ALL cells.[323-325] In some cases, such rearrangements are also accompanied by a Phe232Cys point mutation in CRLF2 that promotes constitutive dimerization and cytokine-independent growth.[324,325] CRLF2 rearrangements occur with especially high frequency in patients with Down syndrome[323-325] and have been found to portend a poor prognosis in adults.[324] Interestingly, aberrant CRLF2 expression very frequently co-occurs with JAK2 activating mutations, and these two genetic lesions collaborate to induce ligand-independent activation of downstream signal transduction pathways, suggesting that CRLF2 may act as a scaffold that is required for activation of oncogenic JAK-STAT signaling by JAK2 mutations in B-precursor ALL.[323-325] A number of JAK2 inhibitors have been developed for the treatment of myeloproliferative

syndromes,[326] and these findings have thus generated considerable excitement to the application of such inhibitors to CRLF/JAK2-mutant B-precursor ALL.

Interleukin-7 Receptor Mutations in T-Cell Acute Lymphoblastic Leukemia

The IL-7R α is required for normal T-cell development, with inactivating IL7R mutations leading to severe combined immunodeficiency.[327] The IL-7R protein can heterodimerize with either IL2Rγ, resulting in the receptor for IL-7, or with CRLF2 to form the receptor for thymic stromal lymphopoietin.[328,329] Recently, point mutations in the IL-7R have been described in approximately 10% of T-ALL cases.[53,330,331] These point mutations often introduce a novel cysteine residue in the transmembrane domain of the protein that induces ligand-independent receptor dimerization and activation of downstream oncogenic signal transduction pathways, including JAK–STAT and PI3K–AKT. IL-7R mutations occur in approximately 10% of T-ALL cases and are enriched in the TLX3-rearranged and HOXA-overexpressing cases, thus suggesting the therapeutic utility of targeting this signal transduction pathway in T-ALL.

Mutated Genes

The activation of cellular proto-oncogenes by point mutation is difficult to detect because such lesions lack the cytogenetic abnormalities that signal other forms of transforming alterations. Genes of this type must first be identified in experimental systems so that investigators know in advance the types of activating point mutations that are likely to occur in human tumors. The prototypic genes of this class are NOTCH1 and members of the RAS family, with mutations that affect defined functional domains of the corresponding proteins.

NOTCH1 in T-Cell Acute Lymphoblastic Leukemia

The *NOTCH1* gene was discovered as a partner gene in a t(7;9) chromosomal translocation that is found in exceedingly rare cases of T-ALL in which *NOTCH1* is truncated and placed under the control of the TCR β locus.[332] *NOTCH1* plays several critical roles in promoting T-cell development[40,333-335] and is highly leukemogenic when expressed in murine T-cell precursors.[336] Despite the rarity of translocations involving this gene, a search for activating NOTCH1 mutations demonstrated that these are present in more than 50% of cases of T-ALL, and these occur in all molecular subtypes of T-ALL.[8] NOTCH1 is a transmembrane protein that is proteolytically processed during its transit to the cell surface, where it exists as a heterodimer consisting of extracellular and transmembrane subunits (Fig. 63-5). Upon ligand binding, the transmembrane subunit undergoes additional proteolytic cleavage within the plasma membrane, which leads to the release of its intracellular domain, known as ICN1 (intracellular domain of NOTCH1), into the cytosol. ICN1 subsequently translocates into the nucleus, where it is active as a transcription factor. Activating *NOTCH1* mutations in T-ALL can occur as either missense mutations in the heterodimerization domain, which allow constitutive proteolytic activation of the ICN1 domain,[8,337] or as frameshift mutations or stop codons that lead to truncation of the PEST domain.[8,338] PEST domains are protein sequences rich in proline (P), glutamate (E), serine (S), and threonine (T) that regulate the proteasomal degradation of proteins with short half-lives, thus these PEST-inactivating mutations impair the degradation of ICN1. Mutations in both regions are often found on the same allele in cases of T-ALL, and in experimental systems, mutations in both domains of the same gene indeed are synergistic.[8] Recent work has demonstrated that *MYC* is an important transcriptional target of *NOTCH1,* and it mediates many of the leukemogenic properties of *MYC* in human T-ALL cell lines.[339-341]

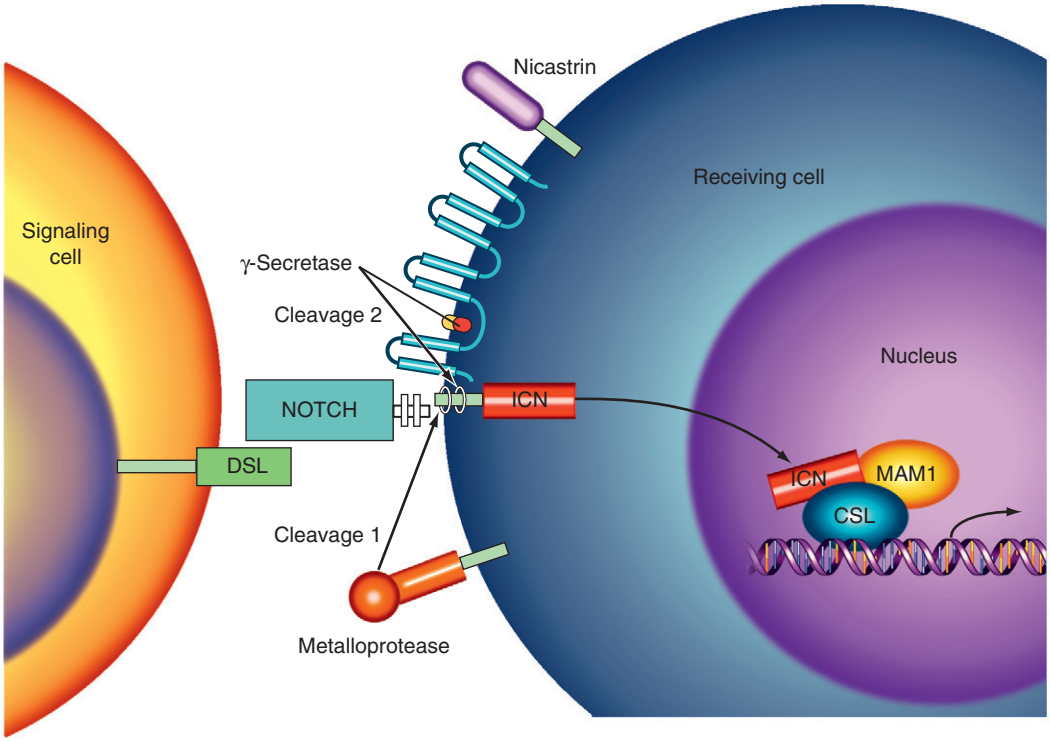

Figure 63-5 ACTIVATION OF NOTCH SIGNALING VIA EXTRACELLULAR AND INTRACELLULAR PROTEOLYTIC CLEAVAGE AND NUCLEAR TRANSLOCATION OF THE INTRACELLULAR NOTCH DOMAIN (ICN). Interaction with δ serrate ligand (DSL) stimulates proteolytic cleavage of NOTCH by metalloproteases and γ-secretase. This leads to the release of the intracellular ICN domain, which translocates to the nucleus, where it acts as a transcription factor to regulate gene expression. *(Adapted from Armstrong SA, Look AT: Molecular genetics of acute lymphoblastic leukemia.* J Clin Oncol *23:6306, 2005, with permission.)*

The proteolytic activation of the ICN domain of NOTCH1 upon ligand binding is mediated by γ-secretase, and γ-secretase inhibitors have previously been developed because of the role of this enzyme in the pathogenesis of Alzheimer disease. These inhibitors inhibit the growth of many T-ALL cell lines,[8,342] and trials of γ-secretase inhibitors in patients with T-ALL are currently underway.

RAS Gene Mutations

Human tumor DNAs were initially found to contain activated homologues of either *HRAS* or *KRAS,*[343,344] proto-oncogenes that were identified on the basis of their homology with viral oncogenes. Gene transfer methods identified an additional member of the RAS gene family, called *NRAS,*[345,346] that had not been observed as a component of a transforming retrovirus. Proto-oncogenes of the RAS family (*HRAS, KRAS,* and *NRAS*) encode 21-kDa proteins that are associated with the inner surface of the cytoplasmic membrane and are involved in growth factor receptor signaling.[347] The *RAS* proto-oncogenes are activated to the status of transforming oncogenes by somatic mutations that alter the amino acids specified by codons 12, 13, or 61. Mutated *RAS* genes lose their intrinsic GTPase activity and become insensitive to GAP proteins, thus accumulating in their active, GTP-bound conformation even in the absence of growth factor binding to surface receptors. Aberrant *RAS*-mediated signaling contributes to transformation through activation of the PI3K (phosphoinositide-3-kinase) and MAPK (mitogen-activated protein kinase) pathways.[347]

Activated *NRAS* genes appear to be preferentially involved in hematopoietic malignancies. They have been detected in myeloid cell lines,[348,349] in fresh leukemic cell samples from patients with AML or CML,[350-352] and in patients with MDS.[353] In ALL, mutations of codons 12, 13, or 61 of *NRAS* have been found in approximately 10% of patients, and *KRAS* mutations have been identified in 5% to 10% of patients.[354,355] *RAS* mutations are particularly common in cases of *MLL*-rearranged B-precursor ALL, in which 40% of cases have *KRAS* mutations and an additional 10% have *NRAS* mutations.[355] Additionally, *RAS* mutations have also been associated with high hyperdiploidy.[356] The presence of RAS mutations does not appear to have prognostic significance in the setting of contemporary treatment regimens.[354]

PTEN–PI3K–AKT Mutations in T-Cell Acute Lymphoblastic Leukemia

The PI3K–AKT signal transduction pathway, which is negatively regulated by the PTEN tumor suppressor, induces cellular growth and proliferation while inhibiting apoptosis and is aberrantly activated in a range of human cancers.[357-359] In T-ALL, recent work has identified a very high frequency of mutational activation of oncogenic signaling through this pathway, most often via deletions or truncating mutations of *PTEN,* but activating mutations of PI3K and AKT genes also occur.[360-363] Moreover, deletions of PTEN have been found to predict treatment resistance in clinical specimens,[53,360] and PTEN inactivation has been shown to induce resistance to inhibition of MYC and of NOTCH1 in zebrafish and murine models of T-ALL, further implicating PTEN loss in T-ALL treatment resistance.[362,364,365] Taken together, these findings thus suggest the potential clinical utility of PI3K-AKT pathway inhibitors in high-risk T-ALL, many of which are currently in human clinical trials.[366]

Gene Amplification

Gene amplification at the DNA level provides the cell a means to increase expression of critical genes whose products are ordinarily tightly controlled. Clinically important examples of proto-oncogene amplification have been documented in solid tumors of both adults and children. The *MYCN* gene, for example, is amplified from 10- to 300-fold in tumor cells from about one-third of cases of childhood neuroblastoma; such amplification has been linked to an advanced stage of disease and a poor prognosis.[367] However, the cytogenetic hallmarks of gene amplification—double-minute chromatin bodies and homogeneously staining regions—are rarely found in karyotypes of human leukemia cells, making it unlikely that high-level amplification of cellular proto-oncogenes is widespread in ALL. However, as noted earlier, the *NUP214–ABL1* fusion oncogene is amplified as a small, cytogenetically undetectable episome in T-ALL.

MYB Duplication in T-Cell Acute Lymphoblastic Leukemia

A duplication of the c-*MYB* gene was recently discovered in cases of T-ALL,[368-370a] and a chromosomal translocation that juxtaposes *c-MYB* to the TCR β gene regulatory elements was also identified in a small number of patients.[369] The discovery of this gene duplication involving a small region of the chromosome was made possible by recent technologic advances that now allow the high-resolution detection of small regions of focal amplifications and deletions. The *MYB* transcription factor is the cellular counterpart of the avian *v-MYB* avian myeloblastosis virus, which causes a rapidly fatal monoblastic leukemia in chickens and is essential for normal hematopoiesis, including T-cell development. The *MYB* duplication is mediated by homologous recombination between identical sequence regions that flank the gene,[370a] and its expression appears to be important in preventing T-lymphoblast differentiation because knock-down of *MYB* expression in T-ALL cell lines induces T-cell differentiation.[368]

Tumor Suppressor Genes

Much attention has been focused on tumor suppressors, whose loss of function via deletion or mutational inactivation leads to malignant transformation. Knudson first proposed that inactivation of both alleles of a single locus is needed to initiate the development of retinoblastoma, basing his hypothesis on the observed frequencies of hereditary and sporadic forms of this disease.[370b] Allelic loss of defined regions of many different chromosomes has been linked to specific types of human tumors. By analogy with the findings in retinoblastoma, a reasonable hypothesis is that each of these regions harbors a tumor suppressor gene whose product is uniquely involved in the inhibition of cell cycle progression and promotion of terminal differentiation of the normal cells that give rise to these different types of tumors. Tumor suppressor genes that play an important role in ALL include *p53* and the *p16* locus.

The *p53* Tumor Suppressor

p53, located on chromosome 17, band p13, is mutated or lost through chromosomal deletion in a wide variety of human tumors,[371] including colon cancer, lung cancer, breast cancer, and osteosarcoma. Heritable cancer-associated changes of the *p53* tumor suppressor gene occur in families with Li-Fraumeni syndrome, an unusual aggregation of sarcomas, brain tumors, leukemias, adrenocortical carcinomas, and premenopausal breast cancers.[372-375] *p53* encodes a 53-kDa transcription factor that functions as a cell cycle and apoptosis checkpoint regulator.[371,376-380] The p53 protein is increased by DNA damage, blocks cell division at G1 to allow DNA repair, and activates apoptosis in cells that have sustained DNA damage.[381-386] The mechanism of p53 activation is triggered by the loss of activity of MDM2 after DNA damage (via ATM) or oncogenic stress (via p14/ARF). As a negative regulator of p53, MDM2 induces the ubiqitination of p53 and its degradation by the proteasome. Hence, when MDM2 activity is abolished, p53 accumulates and certain cell cycle regulatory genes such as *p21*(*WAF1/CIP1/SDI1/CAP20*) and proapoptotic factor genes such as *BAX, PUMA,* and *NOXA* are transcriptionally activated.

p53 is also inactivated in a variety of hematopoietic malignancies, including B-cell ALL and Burkitt lymphoma, but is mutated or

deleted in fewer than 3% of pediatric B-precursor or T-cell ALL cases at diagnosis.[387-389] It thus appears to play a limited role in the etiology of pediatric leukemia. However, *p53* mutations are seen in approximately 25% of relapsed T-cell ALL cases, suggesting a role for *p53* inactivation in the development of resistant disease.[387,388] In addition, *p53* mutations were detected in three of 10 ALL patients who failed on induction therapy or suffered early relapse, further supporting a role for *p53* inactivation in disease progression.[390,391]

The Cyclin-Dependent Kinase Inhibitors

The cyclin-dependent kinase (CDK) inhibitors, which include p15 (INK4B/MTS2), p16 (INK4A/MTS1/CDKN2), p18 (INK4C), p19 (INK4D), p21 (WAF1/CIP1/SDI1/CAP20), p27 (KIP1), and p57 (KIP2)m constitute a family of tumor suppressors that negatively regulate the cell cycle by inhibiting CDK phosphorylation of pRB.[392] The *INK4A* locus, located on the short arm of chromosome band 9q21, contains two different tumor suppressor genes, *p16INK4A* and *p14ARF* (*p19ARF* in mice),[393,394] each with a distinct promoter and first exon but common second and third exons. Despite this close relationship at the genomic level, p16 and p14 have totally unrelated amino acid sequences because they use different reading frames in their common second and third exons.[395] A third tumor suppressor gene, the CDK inhibitor *p15INK4B,* also resides in this region.[396,397] p16INK4A and p15INK4B directly inhibit cyclin D–CDK4/6 complexes and interfere with cell cycle progression. Cyclin D–CDK4/6 complexes promote entry into S phase through phosphorylation of the retinoblastoma protein, PRB, leading to the release of transcription factors, such as E2F, that promote entry into S phase. By contrast, p14ARF lacks a direct effect on the cell cycle machinery, acting instead to stabilize and upregulate p53 through the inhibition of MDM2.[396-400] The role of the *INK4a* locus in tumorigenesis was substantiated when mice with targeted disruption of exon 2 in *p16* developed tumors (primarily lymphomas and fibrosarcomas) whose induction was enhanced by the topical application of carcinogens and ultraviolet light.[401,402] The phenotype of the *p16/p19*$^{-/-}$ mice could be duplicated by selective mutation of the *p19ARF* gene (by targeting the first exon),[393] although mice deficient in *p16INK4A* with intact *p19ARF* also showed increased susceptibility to cancer.[401,402]

The short arm of chromosome 9 is the most frequent target of chromosomal alterations in human cancer. In particular, the human leukemias and lymphomas show a high frequency of 9p21 deletions involving both the *p16INK4A/p14ARF* and the *p15INK4B* loci. Epigenetic silencing of these tumor suppressor genes through hypermethylation of their promoter sequences represents an alternative mechanism of gene inactivation. Although *p16INK4A/p14ARF* and *p15INK4B* are homozygously deleted in 20% to 30% of B-precursor ALL cases and in 70% to 80% of T-cell ALL cases, epigenetic silencing of the p15INK4B promoter has been observed in 44% of primary B-lineage ALLs.[403-415]

FBW7 in T-Cell Acute Lymphoblastic Leukemia

FBW7 is an E3 ubiquitin ligase that targets the transcriptionally active intracellular form of NOTCH (ICN), MYC, and cyclin E for degradation, and this gene is inactivated by mutation or deletion in approximately 10% of T-ALL cases.[416] In T-ALL cell lines, *FBW7* mutation or homozygous deletion leads to resistance of NOTCH pathway inhibition by γ-secretase inhibitor therapy, likely because intracellular NOTCH protein levels remain high in the absence of FBW7-mediated degradation despite inhibition of γ-secretase activity. Additionally, tumor-derived FBW7 mutations maintain their ability to bind MYC but do not lead to its degradation, and these may act as dominant negative mutants that protect MYC from degradation.[416] More recent work has shown that FBW7 also targets the antiapoptotic protein MCL1 for proteasomal degradation in T-ALL, providing an additional oncogenic consequence resulting from inactivation of the FBW7 tumor suppressor.[417]

PAX5 and Other B-Cell Developmental Gene Alterations in B-Precursor Acute Lymphoblastic Leukemia

A recent high-resolution genome-wide analysis of B-precursor ALL cases using single nucleotide polymorphism arrays identified copy number alterations in a number of genes that play important roles in B-cell development.[418] Genes involved in B-cell development were found to be altered by deletion, amplification, mutation, or rearrangement in 40% of cases of B-precursor ALL. The most common abnormalities identified were deletions of *PAX5,* and, upon further analysis in other cases, other mechanisms that led to inactivation of *PAX5* were identified. These included a number of translocations that led to fusion proteins that maintained the ability to bind to PAX5 transcriptional targets but lost regulatory ability, thus having dominant negative activity, and inactivating point mutations that altered the transcriptional activity of *PAX5.* Deletions were also detected in the *TCF3, EBF1, LEF1, IKZF1,* and *IKZF3* genes, all of which play important roles in B-cell development.

Ikaros Mutations in High-Risk B-Precursor Acute Lymphoblastic Leukemia

Ikaros is a DNA-binding transcription factor that is required for the development of all lymphoid lineages, and expression of a dominant negative Ikaros mutation in mice was shown to lead to T-cell lymphomas.[419,420] However, the role of Ikaros in human leukemias was not appreciated until genomic analyses of B-precursor ALL patient samples revealed Ikaros (IKZF1) deletions in 29% of pediatric samples.[418] Ikaros deletions are strongly associated with BCR–ABL-positive ALL, and these are characteristically acquired at transformation of CML to ALL (lymphoid blast crisis).[421] Ikaros deletions predict a very high risk of treatment failure that appears to be independent of BCR–ABL, with patients with Ikaros-deleted, BCR–ABL negative ALL faring similarly poorly to those with BCR–ABL-positive ALL.[422] Interestingly, recent work has implicated mutational activation of CRLF2-JAK2 signaling in Ikaros-deleted, BCR–ABL-negative ALL.[423] Given the remarkable clinical activity of imatinib in high-risk BCR–ABL ALL, these findings thus suggest the need for clinical trials of small molecule inhibitors of JAK-STAT signaling in this high-risk subtype of B-precursor ALL.

Inactivation of LEF1 in T-Cell Acute Lymphoblastic Leukemia

The LEF1 transcription factor, a member of the LEF/TCF (lymphoid enhancer binding factor/T-cell specific transcription factor) family of DNA-binding transcription factors, is best known for its role as a positive mediator β-catenin transcriptional activity, a well-established oncogene.[424] Recent genomic analyses have identified mono- and biallelic deletions and truncating mutations of LEF1 in 18% of primary T-ALL patient samples, unexpectedly implicating LEF1 as a T-ALL tumor suppressor.[425] LEF1 inactivation is associated with a very young age at diagnosis, T-cell differentiation arrest at an early cortical stage of T-cell development, and activating NOTCH1 mutations. Moreover, T-ALL cases with LEF1 inactivation are characterized by the highest expression of MYC mRNA of any T-ALL subtype, a surprising finding given that LEF/TCF transcription factors transactivate MYC expression when bound to β-catenin.[426,427] In addition to their well-established functions as transcriptional activators, LEF/TCF transcription factors can also act as transcriptional repressors when bound to Groucho/TLE family members in the absence of β-catenin activation.[428] Although the precise mechanisms responsible for the pathogenic effect of LEF1 inactivation in T-ALL have not yet been established, these findings thus suggest the intriguing possibility that LEF1 may actively repress MYC in T-ALL cells lacking β-catenin

activation, and that LEF1 inactivation in this context may promote maximal MYC overexpression downstream of other oncogenic lesions that drive MYC overexpression, such as NOTCH1 mutations.

BCL11B Inactivation in T-Cell Acute Lymphoblastic Leukemia

The BCL11B transcription factor is required for normal T-cell development. In murine T-cell progenitors, inactivation of BCL11B leads to developmental arrest at DN stages, acquisition of NK-like features, and aberrant self-renewal activity.[429-432] Monoallelic BCL11B deletions or point mutations have recently been identified in 9% to 16% of primary T-ALL patient samples.[149,433] The point mutations identified typically occur within the DNA-binding domains of BCL11B and are predicted to disrupt their ability to bind DNA. Moreover, previous work in murine models has shown that BCL11B suppresses T-lymphoblastic malignancies induced by p53 haploinsufficiency, radiation, or the BCR–ABL oncogene,[434,435] and BCL11B inactivation is a particularly common cooperating lesion in murine T-ALL induced by the TLX1 oncogene or by ATM deficiency.[149,436] In human T-ALL, recurrent cryptic t(5;14)(q35;q32) translocations juxtaposing BCL11B and TLX3 have been described, which result in BCL11B gene regulatory elements driving overexpression of TLX3.[103,437,438] These translocations were long thought to be pathogenic because of the resultant overexpression of the TLX3 oncogene. However, these recent findings indicate that both BCL11B inactivation and TLX oncogene overexpression are important pathogenic consequences of this translocation, thus representing two oncogenic events from a single genomic lesion.

PHF6 Mutations in T-Cell Acute Lymphoblastic Leukemia

T-ALL has a conspicuous male predominance, suggesting the potential involvement of tumor suppressors on the X-chromosome. Targeted mutational analysis of the X chromosome revealed one such candidate tumor suppressor, PHF6, which encodes a nucleolar protein of unknown function whose germline mutation leads to the Borjeson-Forssman-Lehmann syndrome (OMIM 301900), which is associated with severe mental retardation and facial dysmorphisms but is not known to be associated with T-ALL. Somatic PHF6 mutations were identified in 16% of pediatric and in 38% of adult T-ALL patient samples, were most often nonsense or frameshift mutations, and were associated with overexpression of the TLX1 or TLX3 oncogenic transcription factors.[439] The pathogenic consequences of PHF6 inactivation in T-ALL are presently unknown but are a matter of active investigation.

Abnormalities of Leukemia Cell Ploidy

Abnormalities of chromosome number, which generally occur in the absence of specific chromosomal translocations, have important prognostic implications in childhood ALL. Found in 25% to 30% of childhood ALL cases, hyperdiploidy of more than 50 chromosomes in the leukemic clone is one of the most powerful means of identifying patients with a very good prognosis.[91,258] In particular, trisomies of chromosomes 4, 10, and 17 impart a particularly good prognosis, and hyperdiploidy in the absence of these trisomies is less of a favorable prognostic factor.[440] As mentioned previously, activating mutations of *FLT3,* a receptor tyrosine kinase, are common in these patients. Patients with hyperdiploidy typically present with favorable prognostic indicators, such as age between 2 and 10 years, a low white blood cell count, and an early pre-B immunophenotype, and can expect cure rates that approach 90%.[441-443] The mechanism accounting for the favorable outcome of patients with hyperdiploid ALL remains elusive but may reflect an increased sensitivity to antimetabolite therapy[444] and a greater propensity to undergo apoptosis.[445] Conversely, hypodiploidy (<45 chromosomes) carries an extremely poor prognosis.[91,258,446] Overall, adults with ALL have significantly fewer numeric chromosomal abnormalities than do children; however, abnormalities of ploidy do also appear to have prognostic significance in adults because one large series demonstrated a favorable prognostic impact of hyperdiploidy, but adults with hypodiploidy had extremely poor outcomes.[33]

CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA: A MODEL FOR GENE-BASED RISK ASSESSMENT

Many of the chromosomal and molecular genetic abnormalities in the leukemic blasts of patients with B-precursor ALL are important predictors of response to currently available chemotherapy. Lymphoblasts from each new case of childhood ALL should be examined for molecular prognostic markers, including leukemia cell ploidy, *MLL* gene rearrangements, and the presence of *BCR–ABL* and *TEL–AML1* fusion transcripts. Additional clinical criteria that have prognostic significance, such as the age of the patient, the peripheral blood white blood cell count at diagnosis, and the presence of CNS involvement, are used by modern pediatric ALL treatment regimens to further adjust the intensity of therapy to an individual patient's risk of relapse. It is also worth noting that B-precursor ALL in patients younger than 1 year of age is associated with an extremely poor prognosis secondary to an exceedingly high rate of relapse, which is at least partly attributable to the very high frequency of MLL translocations in this population, and these patients are typically treated with unique treatment regimens designed specifically for infant ALL. In T-ALL, the paucity of clinically useful prognostic markers has greatly hindered progress toward personalized therapy, but the recent identification of differentiation arrest at the earliest stages of T-cell development as a marker of very poor prognosis,[50,51] together with the identification of mutations and gene expression signatures that closely resemble those of AML and HSCs,[52,53] has generated considerable excitement for the application of intensified, AML-like treatment regimens to this high-risk subset of T-ALL. Finally, response to treatment has independent prognostic significance. Induction failure, often defined in pediatric protocols as any morphologic evidence of leukemia at the end of the initial month of induction chemotherapy, represents a very poor prognostic factor and is an indication for BMT after remission is achieved in most centers. Additionally, sensitive flow cytometric and polymerase chain reaction–based methodologies for the detection of minimal residual disease (MRD) are now available, and the level of MRD after induction chemotherapy has recently been shown to provide an additional means of identifying patients at low or high risk of relapse.[447,448] With the availability of these prognostic indicators, there remains little justification for uniform treatment of newly diagnosed cases of ALL. Rather, modern trials emphasize risk-based therapy to reduce toxicity in patients likely to become long-term responders and to intensify therapy for those at high risk of relapse.

A risk classification scheme based on a patient's clinical features and on the genetic features of leukemic blasts has been proposed for patients with B-precursor or T-cell ALL who are 1 year of age or older (Table 63-2). Patients with *TEL–AML1* positivity or with simultaneous trisomies of chromosomes 4, 10, and 17 constitute the lower risk group and are candidates for reduced-intensity treatment regimens. The intermediate-risk group includes patients between the ages of 1 and 9 years with standard-risk age and leukocyte count, as defined by criteria of the National Cancer Institute, and whose leukemic lymphoblasts lack prognostically important genetic features. The high-risk group includes patients who meet any of the following criteria: age 10 years or older, high leukocyte counts at diagnosis, a T-cell immunophenotype, or a slow early response to therapy. Patients in the very high-risk group, defined by extreme hypodiploidy, *MLL* gene rearrangements, the *BCR–ABL* translocation, high MRD at the end of induction chemotherapy, or T-ALL blasts harboring the high-risk early T-cell progenitor (ETP) or absence of biallelic TCRγ deletion (ABD) markers are eligible for BMT in first remis-

Table 63-2 Clinical Risk Assignment in Childhood Acute Lymphoblastic Leukemia

Risk Group	Features	Recommended Therapy
Low risk	• Simultaneous trisomies of chromosomes 4, 10, 17 • *TEL–AML1* fusion	Less intensive antimetabolite-based chemotherapy
Intermediate risk	• Standard-risk age or leukocyte count without other genetic risk features	Intermediate antimetabolite-based chemotherapy
High risk	Presence of any of the following: • Age 10 years or older • T-cell immunophenotype • WBC count >50,000/mm^3 • CNS leukemia	Intensified multiagent chemotherapy with cranial radiation
Very high risk	• *BCR–ABL* translocation* • *MLL* translocations†‡ • Hypodiploidy <45 chromosomes • Induction failure or elevated MRD at the end of induction chemotherapy • T-ALLs with early T-cell progenitor (ETP) or absence of biallelic TCRγ deletion (ABD) markers	Allogeneic bone marrow transplantation in first remission

ALL, Acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *CNS,* central nervous system; *MRD,* minimal residual disease; *TCR,* T-cell receptor; *WBC,* white blood cell.
*Recent data also indicate excellent 3-year survival rates with the use of imatinib, a targeted BCR-ABL inhibitor, in combination with conventional chemotherapy.
†Current evidence suggests that bone marrow transplantation in first remission may not improve outcomes for children with MLL-rearranged ALL.
‡Although *MLL* translocations are almost always associated with very poor outcomes, patients with T-cell ALL who have the t(11;19) MLL-ENL translocation appear to have excellent outcomes with conventional chemotherapy.

sion. It is worth noting that the evidence supporting a benefit for BMT in first remission is especially strong in the presence of the *BCR–ABL* translocation, although its benefit in *MLL*-rearranged ALL remains unclear. Moreover, recent data in the setting of BCR–ABL ALL indicate that the combination of imatinib (a BCR–ABL inhibitor) with conventional chemotherapy leads to excellent short-term (3-year) survival rates, although longer follow-up will be required to ensure that long-term outcomes are comparable. Among several exceptions to this risk stratification criteria are T-ALL patients with the t(11;19) and expression of *MLL-ENL,* who have a favorable prognosis,[17,449] and infants younger than 1 year of age, in whom separate risk stratification criteria have been devised. The incorporation of highly predictive risk stratification methods into clinical trials, together with the development of novel molecularly tailored therapies, should eliminate the still significant risk of relapse in patients with newly diagnosed ALL, ensuring permanent cure without the hazard of acute or chronic complications.

FUTURE DIRECTIONS

The immediate applications of the emerging molecular information include a redefinition of risk classification schemes to emphasize the roles of somatically acquired genetic abnormalities that carry a defined prognosis and likelihood of therapeutic failure. Currently, patients are assigned to treatment according to their initial clinical features and, increasingly, the genetic and biologic properties of their leukemic cells. We are now in a position to view ALL as a group of heterogeneous diseases defined by discrete molecular lesions. As these lesions have been systematically analyzed in larger numbers of patients, it has been possible to devise new classification schemes for ALL that reflect prognosis with exquisite precision. The development of new drugs based on the molecular biology of ALL, whose promise is highlighted by the early success of imatinib in BCR–ABL–positive ALL, is clearly a priority for the future and will likely take the form of compounds developed to specifically interfere with oncoproteins expressed by each patient's leukemic blasts. Additionally, the discovery that several kinases play important roles in ALL pathogenesis has provided new opportunities for targeted drug development. The opportunity is now at hand to improve therapy through randomized trials coordinated on a nationwide or even worldwide scale that focus on key subsets of acute leukemia patients whose lymphoblasts harbor specific genetic abnormalities.

CHAPTER 64

CLINICAL MANIFESTATIONS AND TREATMENT OF ACUTE LYMPHOBLASTIC LEUKEMIA IN CHILDREN

Sima Jeha and Ching-Hon Pui

Serial risk-directed clinical trials have optimized the combination of chemotherapeutic agents and, along with advances in supportive care, have led to current cure rates of childhood acute lymphoblastic leukemia (ALL) exceeding 85% compared with long-term survival less than 10% in the 1960s.[1] However, because ALL is the most common cancer in children, relapsed ALL remains the leading cause of death from a disease in this age group. Over the past decade, minimal residual disease (MRD) has become a major determinant in risk stratification, cranial irradiation has been successfully omitted from some frontline protocols, and the tyrosine kinase inhibitor (TKI) imatinib has revolutionized the treatment of patients with *BCR-ABL1* rearrangement. Our understanding of the immunology and molecular pathways involved in ALL is improving at a rapid pace, and several targeted therapies are showing promise in early clinical trials. The challenge is to successfully incorporate targeted therapy into personalized ALL regimens aiming at improving cure rates and reducing toxicity.[2]

EPIDEMIOLOGY

Acute lymphoblastic leukemia accounts for approximately 75% of all cases of childhood leukemia and is the most common pediatric cancer in developed countries, representing 23% of cancer diagnoses among children younger than 15 years of age. About 2400 children and adolescents are diagnosed with ALL each year in the United States, an annual rate of 30 to 40 per million. The peak incidence of ALL occurs around 4 years of age. This young age peak historically has appeared at different times in different countries and has been associated with major periods of industrialization, suggesting a causative role for environmental carcinogens. ALL occurs more frequently in boys than in girls at all ages.[3]

Acquired and inherited genetic factors play an essential role in ALL as supported by the demonstration of genetic abnormalities in leukemic cells of children with ALL as well as by clinical observations. Children with the constitutional chromosomal abnormality trisomy 21 (Down syndrome) are up to 15 times more likely to develop leukemia than children without Down syndrome. Genetic instability and DNA repair disorders (e.g., Bloom syndrome, ataxia telangiectasia, Fanconi anemia) are also associated with an increased risk of developing ALL.[4] Among identical twins, if one is diagnosed with ALL during the first year of life, the risk that the other twin will develop ALL is more than 70%, approaching 100% in twins with a single monochorionic placenta. Highest in infancy, this risk diminishes with increasing age at diagnosis in the first twin to about one in 10 in older children. If the first twin develops ALL by 5 to 7 years of age, the risk to the second twin is at least twice that in the general population, regardless of zygosity.[5] After the age of 7 years, the risk to the unaffected twin is similar to that for persons in the general population. The extraordinarily high concordance rate in monozygotic infants twins compared with dizygotic infant twins or nontwinned siblings results from the metastasis of leukemic cells from one twin to the other through shared placental circulation. The majority of infants with ALL have a chromosome translocation that results in the fusion of the *MLL* gene at 11q23 with a variety of partner genes but principally AF4. Identical twin infant pairs with concordant ALL share the same acquired *MLL* gene rearrangements.

The most common chromosome translocation in childhood ALL, t(12;21), results in ETV6(TEL)-RUNX1(AML1) fusion. In contrast to *MLL*-rearranged ALL, *ETV6-RUNX1* leukemias present after infancy and have a concordance rate of only 10% in identical twins. *ETV6-RUNX1* fusion can be found in as many as 1% of cord blood samples of normal newborn babies, a frequency 100 times higher than the prevalence of this subtype of leukemia, suggesting that additional postnatal mutations are necessary for malignant transformation. Analysis of Guthrie cards of 2- to 6-year old children with ALL showed that most did have detectable, clonotypic *ETV6-RUNX1* sequences at birth. In addition, identical *ETV6* and *RUNX1* breakpoints were present in each of twin pairs with a very asynchronous diagnosis, supporting the requirement for one or more additional postnatal events after in utero initiation. This interpretation suggests that *ETV6-RUNX1* initiates leukemogenesis but is insufficient for overt disease, and further genetic alterations are required. ETV6 deletions on chromosome 12p, the most frequent additional genetic abnormalities described in cases of ALL with *ETV6-RUNX1,* appear to be subclonal in fluorescence in situ hybridization (FISH) analysis of leukemic cells from nontwin patients. These findings indicate that *ETV6* deletion is a secondary or later event in leukemogenesis and suggest that leukemia might be initiated in utero but requires an essential second postnatal event (two hits).[6]

Several genetic, dietary, and environmental factors have been proposed to modify the risk of leukemia initiation. Children with various congenital immunodeficiency diseases, including Wiskott-Aldrich syndrome, congenital hypogammaglobulinemia, and ataxia telangiectasia, have an increased risk of developing lymphoid malignancies, as do patients under chronic treatment with immunosuppressive drugs. The loss of cellular immune surveillance capability for tumor antigens and the inability to self-regulate lymphoproliferative processes may contribute to malignant transformation in these patients. Absence of exposure to common infections in the first year of life is associated with a higher risk of developing *ETV6-RUNX1*–positive or hyperdiploid ALL in older children. A possible explanation is that in the absence of infection-driven modulation of the naive immune network in infants, subsequent infectious exposures could result in a highly dysregulated response to infections in older children, contributing to leukemogenesis. Exposure to ionizing radiation and certain toxic chemicals could also facilitate the development of acute leukemia. The high incidence of leukemia among survivors of atomic bomb explosions in Japan during World War II is well documented. Among survivors of the atomic bomb, there was no increase in the incidence of leukemia in children exposed to radiation in utero. This experience contrasts with other reports of an increased incidence of ALL in children exposed to medical diagnostic radiation both in utero and in childhood. Other evidence linking most environmental exposures to risk of childhood ALL has largely been inconsistent. Causation pathways are likely to be multifactorial, and it is probable that the risk of ALL from environmental exposure is influenced by genetic variation through the coinheritance of multiple low-risk variants.

PATHOBIOLOGY

Acute leukemias comprise a group of clonal disorders of maturation at an early phase of hematopoietic differentiation. ALL subtypes are a heterogeneous group of malignancies with distinctive immunophenotype and molecular pathogenesis that result in varying clinical characteristics and response to therapy. Accurate pathobiologic diagnosis is not only important for prognostic stratification but can also help define patient-specific therapeutic approaches.[7]

Lymphoblastic leukemias can arise from either B- or T-cell mutant hematopoietic cells capable of indefinite self-renewal. T-cell ALL can be classified into several distinct genetic subgroups that correspond to specific T-cell development stages and is frequently associated with translocations of T-cell receptor genes on chromosome 14q11 or 7q34 with other gene partners. Recent studies have identified a novel high-risk immature T-cell subtype termed *early T-cell precursor* (ETP) ALL with immunologic markers and gene expression reminiscent of double-negative 1 thymocyte that retains the ability to differentiate into both T-cell and myeloid, but not B-cell, lineages.[8] The discovery of its mutational spectrum recapitulated that of acute myeloid leukemia (AML) by whole-genome sequencing and a global transcription profile similar to that of normal hematopoietic stem cells (HSCs) and granulocyte macrophage precursors suggests that this subtype of leukemia is a stem cell leukemia. The prevalence of mutations in genes regulating cytokine receptor and Ras signaling, and histone modification further suggests that the addition of myeloid-directed therapy might improve the outcome of this subtype.[9] Most B-lineage leukemias are early precursor B cell, expressing CD19 and CD10 (or cALLa, the common acute leukemia antigen) but lacking surface or cytoplasmic immunoglobulin. The mature B-cell ALLs, or Burkitt-cell leukemia, are stratified separately and are not included in this chapter (see Chapters 81 and 83).

Recent advances in global genome analysis have enabled the identification of recurring alterations in genes and pathways with key roles in cell growth and tumorigenesis. Several observations suggest that multiple lesions are acquired subsequent to founding translocations to induce leukemogenesis. Single nucleotide polymorphism (SNP) array analysis demonstrated substantial differences in the frequency of copy number abnormality (CNA) among various ALL subtypes. *MLL*-rearranged cases had less than one CNA per case, suggesting that *MLL* is a potent oncogene that requires very few cooperating lesions to induce leukemia transformation, but *ETV6-RUNX1* and *BCR-ABL1* leukemias have more than six lesions per case.

Deletion or sequence mutation of the *IKZF1,* a gene that encodes the early lymphoid transcription factor IKAROS, is present in more than 80% of *BCR-ABL1*–positive ALL and in a novel high-risk subgroup of *BCR-ABL1*–negative ALL that has a gene expression profile significantly similar to that of *BCR-ABL1*-positive ALL.[10] The "*BCR-ABL1*-like" ALL occurs in as many as 7% to 9% of children with ALL. Approximately half of the *BCR-ABL1*–like cases have rearrangements of the lymphoid cytokine receptor gene *CRLF2,* with concomitant Janus kinases (JAKs) mutations in one-third of the *CRLF2*-rearranged cases.[11] This genotype is associated with high risk of relapse, independent of age, leukocyte count at diagnosis, cytogenetics, and levels of MRD after remission induction. A recent transcriptome sequencing study of 12 cases of *BCR-ABL1*–like cases (with whole-genome sequencing in two of them) identified structural alterations and mutations activating kinase and cytokine receptor signaling in all cases, including *EBF1-PDGFRB, NUP214-ABL1, RANBP2-ABL1, BCR-JAK2, STRN3-JAK2,* and activating mutations of *IL7R* or *FLT3.* Importantly, preclinical studies showed that primary leukemic cells harboring *PDGFRB* or *ABL1* fusion responded to ABL1 TKIs, and those harboring *BCR-JAK2* or mutated *IL7R* responded to JAK2 inhibitor, suggesting that these patients would benefit from the targeted therapy.[12] Another novel subtype of B-cell precursor ALL, characterized by *CRLF2* alterations (*PAR1* deletion and *IGH-CRLF2*), occurs in 5% to 7% of children with ALL and, remarkably, in approximately 50% of the cases with Down syndrome. These patients probably would require more intensive therapy because this genotype was associated with poor outcome in the reported series, albeit not independently significant in one.[13]

Experimental models have established that cooperative mutations are necessary to induce leukemia and contribute to the development of drug resistance. Association studies of ALL based on the candidate gene approach have evaluated a restricted number of polymorphisms in genes implicated in the metabolism of carcinogens, folate metabolism, protection of DNA from carcinogen-induced damage, and cell cycle regulation. Such studies highlight difficulties in conducting statistically and methodologically rigorous investigations into ALL risk. Genome-wide association studies of childhood ALL have recently demonstrated that common variation at four genetic loci [7p12.2 (*IKZF1*), 9p12 (*CDKN2A/CDKN2B*), 10q21.2 (*ARID5B*) and 14q11.2 (*CEBPE)*] confers a modest increase in risk, establishing a role for genetic susceptibility in the development of ALL. In addition to identifying common, low-penetrance susceptibility alleles, these data provide insights into disease causation by identifying risk variants and annotating genes involved in transcriptional regulation and differentiation of B-cell progenitors.

CLINICAL MANIFESTATIONS

Children with ALL present with nonspecific symptoms and signs reflecting the degree of disruption in bone marrow (BM) function and the extent of extramedullary infiltration. The most common presenting symptoms are fever, fatigue, pallor, petechiae, bruising, bleeding from mucosal surfaces, and pain (Table 64-1). Patients, especially young children, may present with bone pain, arthralgia, or refusal to walk because of leukemic infiltration of the bone or joint or because of expansion of the BM cavity by leukemic cells. The evolution of symptoms may proceed over a few days, weeks, or months. Less common presenting symptoms include headache, visual complaints, vomiting, respiratory distress, oliguria, and anuria. Occasionally, patients present with life-threatening infection or bleeding.

On physical examination, fever, pallor, petechiae, and ecchymoses may be present. The lymphoproliferative nature of the disease may

Table 64-1 Clinical Presentation of Acute Lymphoblastic Leukemia

Symptoms and Signs	Etiology	Management
Fever	Disease or infection	Always conduct fever workup and provide broad antimicrobial coverage until infectious etiology is ruled out
Fatigue, pallor	Anemia (ALL infiltrating BM)	RBC transfusion (slow if anemia is severe; avoid in hyperleukocytosis)
Petechiae, bruising, bleeding	Thrombocytopenia (ALL infiltrating BM)	Transfuse with platelets
Pain	Leukemia infiltrating bones or joints or expanding BM cavity	Establish diagnosis and start chemotherapy
Respiratory distress, superior vena cava syndrome	Mediastinal mass	Avoid sedation in the presence of tracheal compression; establish diagnosis as soon as possible and start chemotherapy

ALL, Acute lymphoblastic leukemia; *BM,* bone marrow; *RBC,* red blood cell.

be manifested as lymphadenopathy, splenomegaly, or less commonly hepatomegaly. Central nervous system (CNS) involvement is uncommon at presentation and in most instances is detected by screening lumbar puncture in high-risk patients who are asymptomatic at the time of the puncture **(**Fig. 64-1, *A* and *B*)**.** Papilledema, retinal hemorrhages, and cranial nerve palsies should be ruled out on examination. CNS involvement usually is restricted to leptomeninges, and parenchymal mass lesions are uncommon. Epidural spinal cord compression is a rare but serious presenting finding and requires immediate chemotherapy and high-dose glucocorticoid therapy. Laminectomy or radiotherapy is generally not necessary because leukemias are very sensitive to chemotherapy at diagnosis. Overt testicular involvement occurs in only 2% of boys and usually presents as painless, asymmetric enlargement that can be distinguished from hydrocele by ultrasonography (Fig. 64-1, *C* and *D*). Less common presenting features include ocular involvement, subcutaneous nodules (leukemia cutis) (see Fig. 64-1, *E* and *F*) and enlarged salivary glands (Mikulicz syndrome). Approximately 55% of T-cell cases present with an anterior mediastinal mass. A bulky mediastinal mass can compresses the great vessels and trachea, resulting in superior vena cava syndrome and respiratory distress. Patients with a large mediastinal mass generally present with cough, dyspnea, orthopnea, dysphagia, stridor, cyanosis, facial edema, increased intracranial pressure, and sometimes syncope. When significant tracheal compression is present, general anesthesia should be avoided and procedures should be performed under local anesthesia. Immediate diagnosis and initiation of steroids and chemotherapy is essential to prevent respiratory failure.

Clinical laboratory data often reveal a broad spectrum of abnormal findings. Various degrees of anemia and thrombocytopenia are usually present at diagnosis. The presenting leukocyte counts range widely from 0.1 to 1500×10^9/L. Leukemic blasts may or may not be seen on peripheral smear. Approximately 45% of children have leukocyte counts less than 10×10^9/L, and 15% present with hyperleukocytosis ($>100 \times 10^9$/L). Patients with hyperleukocytosis are at increased risk of CNS disease, tumor lysis syndrome, and leukostasis. Leukostasis may manifest as dyspnea, chest pain, alterations in mental status, cranial nerve palsies, or priapism. The majority of childhood ALL are B cell in derivation with approximately 12% to 15% of children with ALL having a T-cell immunophenotype. T-cell ALL usually occurs in patients older than 9 years of age with elevated leukocyte counts and is associated with CNS involvement. Coagulopathy, usually mild, can occur in T-cell ALL and is only rarely associated with severe bleeding. Elevated serum uric acid and lactate dehydrogenase levels are common in patients with a large leukemic cell burden. Patients with massive renal involvement can have increased levels of creatinine, urea nitrogen, uric acid, and phosphorus. Approximately 0.5% of patients have hypercalcemia at diagnosis, attributable to the release of parathyroid hormone-like protein from lymphoblasts and leukemic infiltration of bone; these patients tend to be in the older age group and present with low blast cell counts. This complication generally resolves rapidly with hydration and chemotherapy. Liver dysfunction caused by leukemic infiltration occurs in 10% to 20% of patients, is usually mild, and has no prognostic consequences. Because vincristine and daunorubicin are metabolized primarily through biliary excretion, modifications of the dosage of these agents are recommended if the direct bilirubin level is elevated.

Abnormalities of the bone, such as metaphyseal banding, periosteal reactions, osteolysis, osteosclerosis, or osteopenia, can be

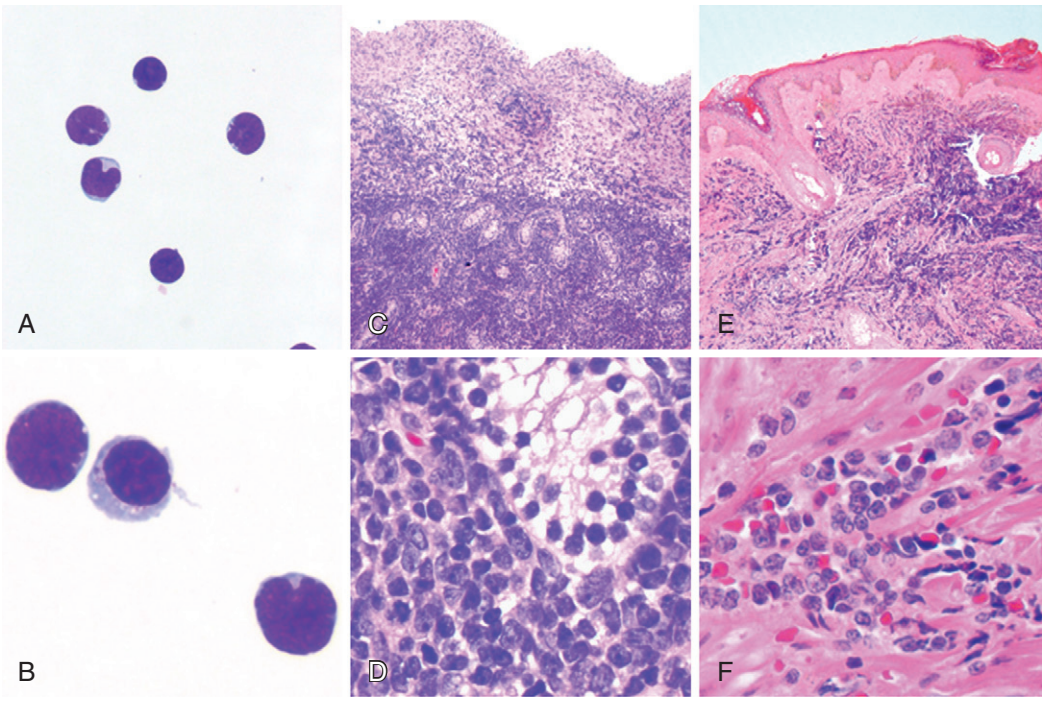

Figure 64-1 CENTRAL NERVOUS SYSTEM (CNS), TESTICULAR, AND SUBCUTANEOUS INVOLVEMENT IN CHILDHOOD ACUTE LYMPHOBLASTIC LEUKEMIA (ALL). CNS disease identified in the cerebrospinal fluid (CSF) by screening lumbar puncture at the time of diagnosis in a 12-year-old boy with high-risk precursor B-cell ALL. The total count of the CSF specimen was 6131/μL with 6076 white blood cells/μL and 98% blasts. **A** and **B,** The cytospin preparation shows mostly blasts, slightly altered morphologically by the preparation. In **B,** there is a small lymphocyte *(middle)* for comparison with the blasts. **C** and **D,** Testicular disease noted at relapse in a 13-year-old boy with precursor B-cell ALL. Note the infiltrate of blasts in the parenchyma of the testes, surrounding the seminiferous tubules. Immunostaining (not shown) demonstrated that the blasts were CD19+, CD10+, and TdT+. **E** and **F,** Cutaneous disease at diagnosis. The patient was an 8-year-old boy with a scalp lesion for 2 months that was initially treated with antibiotics. On biopsy, there was much crush artifact, but deep in the specimen, there was an infiltrate of blasts separating fibers **(F)** shown to be B-cell lineage. Interestingly, the patient had a normal complete blood count, but bone marrow was packed with blasts that had a precursor B-cell phenotype and a hyperdiploid karyotype.

demonstrated by radiographic studies in half of patients, especially those with low presenting leukocyte counts. Vertebral compression fracture can be detected in 2% of the cases, usually with low leukocyte count and hyperdiploidy (>50 chromosomes), and is not associated with adverse prognosis.

DIFFERENTIAL DIAGNOSIS

Children with ALL present with a variety of nonspecific symptoms that may mimic other conditions. Pancytopenia and fever are also presenting symptoms for aplastic anemia. Failure of a single cell line, as in transient erythroblastic anemia, idiopathic thrombocytopenic purpura, and congenital or acquired neutropenia, sometime produces a clinical picture that is difficult to distinguish from ALL. Routine BM aspiration is not necessary for patients with severe thrombocytopenia and no other hematologic or physical evidence of leukemia. However, BM aspiration should be performed to exclude leukemia in patients who require glucocorticoid treatment. Children with infectious mononucleosis or other acute viral illnesses may present with fever, adenopathy, splenomegaly, lymphocytosis, or pancytopenia. Fever, arthralgias, or a limp may frequently be confused with juvenile rheumatoid arthritis, which can also be associated with anemia, leukocytosis, and mild splenomegaly. Children with prominent bone pain frequently have nearly normal blood counts, a finding that can contribute to a delay in diagnosis. Immunostains and molecular studies help differentiate ALL from AML and other small blue cell malignancies that invade the BM, including neuroblastoma, rhabdomyosarcoma, Ewing sarcoma, and retinoblastoma. Infants may present with subcutaneous nodules (leukemia cutis) that look clinically like Langerhans cell histiocytosis.

PROGNOSIS

Contemporary regimens have abolished the prognostic impact of many clinical and biologic features, demonstrating that the single most important prognostic factor in childhood ALL is appropriate risk-directed therapy (Table 64-2). Accurate assessment of relapse hazard is an integral part of ALL therapy, so that only high-risk patients are treated aggressively, with less toxic therapy reserved for cases at lower risk of failure.

To facilitate comparison of treatment results among different clinical trials, participants in a 1993 workshop sponsored by the United States' National Cancer Institute adopted a uniform risk classification based on age and leukocyte count. Two-thirds of the patients who were 1 to 9 years old with precursor B-cell ALL and a leukocyte count less than 50×10^9/L were considered to be at standard risk of relapse; the other third was classified as high risk. This classification proved to be of limited prognostic value because up to one-third of patients designated as standard risk may relapse, and these criteria cannot be applied to T-cell ALL. Moreover, the prognostic impact of age and, to a lesser extent, leukocyte count is largely attributable to their association with specific genetic abnormalities. For example, the overall poor prognosis of infants younger than 12 months of age can be explained by the very high frequency of *MLL* rearrangements (70%–80%) in this age group,[14] and the overall favorable outcome of patients ages 1 to 9 years is related to the preponderance of cases (70%) with hyperdiploidy (>50 chromosomes) or *ETV6-RUNX1* (also known as *TEL-AML1*) fusion, which are both favorable genetic features. Thus a more reasonable strategy is to develop clinical prognostic risk categories based on their major immunophenotypic features and genetic characteristics.

Early pre-B ALL, lacking immunoglobulin synthesis, is the most common form of acute leukemia in children. The high-risk features previously ascribed to pre-B ALL (presence of cytoplasmic immunoglobulin M) are closely associated with the presence of the t(1;19) translocation and *E2A–PBX1* fusion. Prognostic distinctions among ALL immunophenotypes, including the negative prognostic impact once associated with T-cell ALL and pre-B ALL with *E2A-PBX1* fusion, have been abolished by recent improvements in risk-directed treatment. Aberrant expression of myeloid-associated antigens has been observed with certain genetic subtypes. CD15, CD33, and CD65 are expressed in ALL cases with a rearranged *MLL* gene, and CD13 and CD33 are expressed in cases with the *ETV6-RUNX1* fusion. Once associated with a poor outcome in some studies, myeloid-associated antigen expression has no prognostic impact in contemporary risk-directed treatment programs. The recently identified ETP ALL subtype is characterized by immature genetic and immunophenotypic features (CD1a negative, CD8 negative, and CD5 weak and the expression of stem cell or myeloid markers) and a dismal prognosis with conventional therapy.[9]

Acute lymphoblastic leukemia can be classified according to modal chromosomal number (ploidy) and specific genetic abnormalities of the leukemia stem line. Hyperdiploidy (>50 chromosomes per cell) is associated with an age of 1 to 10 years, a lower median leukocyte count, increased sensitivity to antimetabolite agents, and a favorable prognosis. A hypodiploid karyotype (<44 chromosomes per cell), by contrast, predicts a poor outcome. Molecular analysis can identify prognostically and therapeutically relevant subgroups that cannot be identified by karyotyping. *ETV6-RUNX1,* the most common specific genetic rearrangement in childhood ALL, has been associated with a good prognosis. With the exception of T-cell ALL with the t(11;19), the prognosis of cases with 11q23/*MLL* rearrangements is generally poor.

Genetic features do not entirely account for treatment outcome, and their prognostic impact also depends on the treatment efficacy. Although up to 15% of patients with hyperdiploidy greater than 50 chromosomes per cell or *ETV6–RUNX1* fusion have recurrences of their leukemia, a substantial proportion of the patients with the t(9;22) and *BCR-ABL1* fusion who are 1 to 9 years old and have low leukocyte counts at diagnosis may be cured with intensive chemotherapy alone.[15] Among patients with *MLL–AF4* fusion, infants and adults have a worse prognosis than children. Interindividual variability in the pharmacokinetics and pharmacodynamics of many antileukemic agents also contributes to the heterogeneity in treatment response among patients with specific genetic abnormalities.[16]

The degree of reduction of the leukemic cell clone early during remission induction therapy is determined by both leukemic cell genetics and host pharmacogenetics and has shown greater prognostic strength than any other individual biologic or host-related feature.[17] Measurements of MRD by flow-cytometric detection of aberrant immunophenotypes or by polymerase chain reaction (PCR) of clonal antigen–receptor gene rearrangements provides a level of sensitivity and specificity that cannot be attained by traditional morphologic assessment of early treatment response. Patients who achieve an immunologic or molecular remission, defined as leukemic involvement of less than 10^{-4} nucleated BM cells on

Minimal Residual Disease

The rapidity of response to induction therapy is an important independent predictor of outcome. There is strong concordance between the assessment of MRD by flow cytometry and by PCR methods. We (the authors) monitor MRD using primarily flow cytometry methods, which are simple and rapid, and we reserve PCR methods for the few patients (<5%) whose leukemic cells lack a suitable immunophenotype. About half of all patients show a disease reduction to 10^{-4} or lower after only 2 weeks of remission induction, and these patients appear to have an exceptionally good treatment outcome. Persistence of MRD of 10^{-4} or more at 4 months from diagnosis is associated with an especially dismal outcome. The adverse prognosis of high-risk slow early responders can be improved with intensification of induction and consolidation. Standard-risk cases may be spared the increased risk of early morbidity and mortality from intensive induction, provided that they receive postinduction intensification therapy.

Table 64-2 Prognostic Factors in Acute Lymphoblastic Leukemia

Factor	Prognosis	Clinical Application
Age		
<1 yr	MLL^+ (70%–80% infants): Poor outcome MLL^- : Same outcome as for older children	MLL^-: Do well on standard ALL therapy Potential role for FLT3 inhibitor for MLL+
1–9 yr	Standard risk	ALL biology may change risk
>9 yr	Higher risk	ALL biology may change risk
White Blood Cell Count		
$<50 \times 10^9$/L	Standard risk	ALL biology may change risk
$\geq 50 \times 10^9$/L	Higher risk	ALL biology may change risk
Central Nervous System		
CNS3	Higher risk	Therapy intensification
CNS2 Traumatic lumbar puncture with blasts	Higher risk of CNS relapse	CNS-directed therapy intensification
Testicular	Higher risk	Therapy intensification
Immunophenotype		
T cell	Higher risk	Poor outcome abolished with current therapy
Pre–B cell (cIgM+)	Higher risk	Poor outcome abolished with current therapy
Early pre–B cell	Standard risk	Genetics may change risk
ETP	Dismal prognosis	Ongoing studies exploring effective therapies
Ploidy		
>50 (DI >1.16)	Low risk	Good response to antimetabolites
<44	Higher risk	Therapy intensification
Genetic Alterations		
t(9;22)/*BCR-ABL1*	Higher risk	BCR-ABL inhibitors
t(4;11)/*MLL-AF4*	Higher risk	Potential role for FLT3 inhibitors and hypomethylating agents
t(1;19)/*E2A-PBX1*	Higher risk	Poor outcome cancelled on current therapy
t(12;21)/*ETV6-RUNX1*	Low risk	
IKZF1	Poor prognosis. Present in 80% BCR-ABL1+ and also in BCR-ABL1 like	Potential role for TKI, JAK inhibitors
NUP214-ABL1	High risk	Potential benefits from TKI
CRLF2	In 1/3 BCR-ABL1–like, associated with Hispanic or Latino ethnicity and poor outcome	Potential role for JAK inhibitors
CREBBP	Associated with drug resistance and relapse	Potential benefit from histone deacetylase inhibitors
Minimal Residual Disease		
Day 15 <0.01%	Excellent outcome	No benefit from second delayed intensification
Slow early responders	Higher MRD = Higher risk of relapse	Benefit from augmented delayed intensification
EOI >1%	Dismal prognosis	HSCT in first CR
4 mo >0.1%	Dismal outcome	HSCT in first CR

CNS, Central nervous system; *CR,* complete remission; *DI,* DNA index; *EOI,* end of induction; *HSCT,* hematopoietic stem cell transplantation; *MRD,* minimal residual disease; *JAK,* Janus kinase; *TKI,* tyrosine kinase inhibitor.

completion of remission induction, have a much more favorable prognosis than do those who do not achieve this status. Patients who are in morphologic remission but have a postinduction MRD level of 1% or more fare as poorly as those who do not achieve clinical remission by conventional criteria (≥5% blasts). About half of all patients show a disease reduction to 10^{-4} or lower after only 2 weeks of remission induction, and they appear to have an exceptionally good treatment outcome. The persistence of MRD (≥0.01%) beyond 4 months from diagnosis was associated with an estimated 70% cumulative risk of relapse. Patients with 0.1% MRD or more at 4 months had an especially dismal outcome. Most contemporary clinical trials have incorporated MRD detection into the risk classification system. Although MRD positivity is strongly associated with known presenting risk features, it has independent prognostic strength and is increasingly used in risk stratification of ALL in contemporary regimens.[18]

Currently, pediatric ALL patients are typically classified into three risk groups—low-, intermediate-, and high-risk (also referred to as standard-, high-, and very high-risk)—which are categories based on age, leukocyte count at diagnosis, blast cell immunophenotype, and genotype, as well as early treatment response. More recently, gene expression profiling of leukemic cells by the DNA microarray method

has proved useful in identifying previously unrecognized genes whose expression may have prognostic significance. The predictive power of these newly identified expression signatures requires validation in prospective clinical trials.

THERAPY, INCLUDING STEM CELL TRANSPLANTATION

With the exception of patients with mature B-cell ALL, who are treated with short-term intensive chemotherapy, therapy for patients with ALL is administered over 2 to 3 years. Treatment starts with a 4- to 6-week remission-induction phase aimed at eradicating the initial leukemic cell burden and restoring normal hematopoiesis. The induction phase typically includes the administration of a glucocorticoid (prednisone or dexamethasone), vincristine, and at least a third drug (asparaginase, anthracycline, or both). A three-drug induction regimen appears sufficient for most standard-risk cases, provided they receive intensified postremission therapy. The benefit in long-term survival of using four or more drugs during induction is widely accepted in higher risk patients but less clear in lower risk patients. With this approach, 98% to 99% of patients can attain remission, as defined by fewer than 5% blasts in the BM and a return of neutrophil and platelet counts to near normal levels. Intrathecal chemotherapy is usually initiated at the start of treatment.

After remission induction, consolidation (or intensification) is given to eradicate drug-resistant residual leukemic cells. Therapy is tailored to the leukemia subtype and risk group. All patients benefit from a delayed intensification (or delayed reinduction), consisting of using drugs similar to those used in remission induction therapy after a 3-month period of a less intensive, interim maintenance chemotherapy. Double-delayed intensification with a second reinduction at week 32 of treatment improves outcome in patients with intermediate-risk leukemia but does not benefit patients with rapid early response. An augmented intensification regimen consisting of the administration of additional doses of vincristine and asparaginase during the myelosuppression period after delayed intensification and sequential escalating-dose parental methotrexate followed by asparaginase improved the outcome of high-risk patients whose disease had responded slowly to initial multiagent induction therapy.

After completion of induction and consolidation, patients receive a 2- to 2.5-year continuation (or maintenance) phase consisting of low-intensity metronomic chemotherapy designed to eradicate any residual leukemic cell burden. Weekly low-dose methotrexate and daily oral mercaptopurine form the backbone of most continuation regimens. Many groups add regular pulses of vincristine and corticosteroids to this regimen, although the benefit of these pulses and their optimal duration and frequency of administration in the context of contemporary therapy has not been established.[19] Adjusting chemotherapy doses to maintain a white cell count between 2 to 3×10^9/L and neutrophil counts between 0.5 and 1.5×10^9/L has been associated with a better clinical outcome. Overzealous use of mercaptopurine, to the extent that neutropenia necessitates chemotherapy interruption, reduces overall dose intensity and is counterproductive. The optimal duration of therapy remains unknown. Attempts to shorten therapy duration from 24 months to 12 or 18 months have resulted in a significant increase in relapses. Several studies showed no advantage to prolonging treatment beyond 3 years. A small number of patients with particularly poor prognostic features may undergo BM transplantation during first remission.

Radiation therapy was the first modality that was successfully used to prevent CNS relapse. The effectiveness of cranial radiation as preventive therapy was offset by substantial late effects in long-term survivors, including learning disabilities, multiple endocrinopathies, and an increased risk of second malignancies. Subsequent trials demonstrated that in the context of optimal systemic and intrathecal therapy, cranial irradiation can be reduced or even omitted altogether. Patients with high-risk genetic features, large leukemic cell burden, T-lineage ALL, and leukemic cells in the cerebrospinal fluid, even from iatrogenic introduction from a traumatic lumbar puncture at diagnosis, are at increased risk of CNS relapse and require more intense CNS-directed therapy.[20] Studies have successfully used triple intrathecal therapy with methotrexate, hydrocortisone, and cytarabine or intrathecal methotrexate alone. Systematically administered agents, including high-dose methotrexate, dexamethasone, and asparaginase, also contribute to prevention of extramedullary relapse.

Based on reports of more potent in vitro antileukemic activity and better CNS penetration, dexamethasone has replaced prednisone in many continuation regimens. Prednisone remains the preferred glucocorticoid during induction because of the relative increased toxicity associated with dexamethasone use.[21] Polyethylene glycol–conjugated asparaginase, a long-acting and less allergenic form, is progressively replacing the native *Escherichia coli* and is being increasingly administered intravenously instead of intramuscularly. Asparaginase derived from *Erwinia chrysanthemi* has a short half-life, and its use is currently limited to patients who are allergic to the *E. coli* formulations. The dose schedule for asparaginase should take into account the variability in the pharmacokinetic profile and potency among the different preparations.[22] Intensifying asparaginase therapy during the early phase of treatment benefits high-risk patients, particularly those with T-cell disease. Significant improvement was also reported in the outcome of patients receiving early intensification consisting of intermediate- or high-dose antimetabolite therapy.[23] The optimal dose of methotrexate depends on the leukemic cell genotype and phenotype, as well as host pharmacogenetic and pharmacokinetic parameters. Methotrexate at 2.5 g/m^2 is adequate for most patients with standard-risk B-cell precursor ALL, but a higher dose (5 g/m^2) may benefit those with T-cell or high-risk B-cell precursor ALL. This observation is consistent with the finding that T-lineage blast cells accumulate methotrexate polyglutamates less avidly than do B-lineage blast cells. The increased ability of hyperdiploid ALL blasts cells to accumulate methotrexate polyglutamate could partially explain the excellent outcome

Consolidation Therapy

The importance of a consolidation phase after remission induction is undisputed, but the treatment regimen and duration vary in the different childhood ALL studies. Commonly used strategies include high-dose methotrexate plus mercaptopurine, frequent pulses of vincristine and corticosteroid plus high-dose asparaginase for 20 to 30 weeks, and reinduction treatment with the same agents given during initial remission induction. Reinduction treatment has become an integral component of contemporary protocols. In one randomized study, double reinduction further improved treatment outcome in patients with intermediate-risk ALL, but additional pulses of vincristine and prednisone after a single reinduction course were not beneficial, suggesting that the increased dose intensity of other drugs, such as asparaginase, was responsible for the observed improvement. An "augmented" regimen including Capizzi methotrexate (escalating-dose intravenous methotrexate with no rescue followed by asparaginase) and additional doses of vincristine and asparaginase during periods of myelosuppression improved the outcome of patients with a slow early response to therapy.

High-Risk Central Nervous System Relapse

Patients with the following characteristics are at increased risk of CNS relapse and require more intense CNS-directed therapy:

1. Patients with high-risk genetic features
2. Large leukemic cell burden
3. T-lineage ALL
4. CNS-3 status (>5 WBC/μL CSF with presence of lymphoblasts on Cytospin)
5. CNS-2 status (<5 WBC/μL CSF with lymphoblasts)
6. Traumatic CSF with blasts

of children with hyperdiploid greater than 50 chromosomes per cell ALL treated on low-intensity antimetabolite-based regimens. Leucovorin rescue is necessary after treatment with high-dose methotrexate; however, overzealous rescue might counteract the antileukemic activity of methotrexate. Although the intensive asparaginase and high-dose methotrexate treatment has significantly improved the outcome for patients with T-cell ALL, the emergence of specific therapy such as the purine nucleoside analog nelarabine will likely increase the tendency to assign patients with T-cell ALL to a specific treatment protocol or strata.

It is generally recommended to give mercaptopurine at bedtime to patients with an empty stomach and to avoid taking it together with milk or milk products that contain xanthine oxidase, an enzyme that can degrade the drug. About 10% of the population inherit one wild-type gene encoding thiopurine methyltransferase (TPMT) and one nonfunctional variant allele, resulting in intermediate enzyme activity, but one in 300 people inherits two nonfunctional variant alleles and are completely deficient of this enzyme that catalyses the S-methylation of mercaptopurine to its inactive metabolite. Patients with heterozygous and especially homozygous deficiency of TPMT are at high risk of severe myelosuppression. Identification of these patients allows physicians to selectively guide reductions in mercaptopurine dosage without modifying the dose of methotrexate. Substituting thioguanine for mercaptopurine during continuation therapy was associated with a high incidence of profound thrombocytopenia and hepatic venoocclusive disease. Thioguanine use has therefore been limited to short pulses administered during consolidation therapy in some trials; mercaptopurine is selected for prolonged administration.

Because optimizing the administration of existing therapies is reaching its limit, further improvements in outcome will require the development of therapeutic approaches directed against rational therapeutic targets. An example is the significant improvement in the outcome of Philadelphia chromosome–positive (Ph+) ALL with the advent of TKIs targeting the constitutively active *BCR-ABL1* TKI in ALL subset. Ph+ ALL has historically had an extremely poor outcome, but recent studies have demonstrated dramatic improvements in treatment outcome with incorporation of *BCR-ABL1* inhibitors into Ph+ ALL treatment.[24] Recent identification of novel chimeric fusions involving kinases in ALL (e.g., NUP214–ABL1 and STRN3–JAK2) suggests that additional high-risk cases may benefit from targeted therapies directed at kinase signaling.

The expanded understanding of the biologic, immunologic, and genetic heterogeneity of ALL has enabled development of several novel therapeutic strategies.[25] Various monoclonal antibodies are showing promise in early clinical trials and may be incorporated into ALL regimens in the future.

Autologous transplantation has failed to improve outcome in ALL. Comparisons between allogeneic HSC transplantation (HSCT) and intensive chemotherapy have yielded inconsistent results because of the small numbers of patients studied and differences in case selection criteria. It is generally accepted that allogeneic HSCT is a treatment modality for patients with ALL who are predicted to respond poorly to intensive chemotherapy.[26] At present, patients with refractory leukemia (failure to enter morphologic remission after 4–6 weeks of induction therapy), high level of MRD (>1%) after remission induction, persistent MRD after consolidation treatment, and early hematologic relapse are candidates for allogeneic transplantation. It is crucial to reduce residual disease to, or close to, undetectable levels as outcome is superior if MRD is undetectable before HSCT and worsens with increasing MRD levels at the time of HSCT. Treatment approaches for adolescents and young adults with ALL have evolved considerably with the widespread adoption of pediatric-based protocols, which appears to have significantly improved survival and decreased the need for HSCT in this age group. The benefit of allogeneic HSCT in infants with t(4;11) ALL remains controversial and should be evaluated in the context of emerging molecular therapies such as FLT3 inhibitors and DNA methyltransferase inhibitors. Patients with the recently identified ETP ALL have a dismal prognosis (event-free survival of 22%), even though half of the patients received transplantation because of high MRD levels after remission induction. The therapeutic role of HSCT in this group of patients remains to be determined by studying a larger number of patients. Matched unrelated-donor or cord blood transplantation has yielded outcomes comparable to those obtained with matched related-donor HSCT and should be considered reasonable alternatives if a matched donor is not available. Many advances have been made in stem cell transplantation, such as prevention of graft-versus-host disease (GVHD), expansion of the pool of suitable unrelated or related donors, donor selection and tissue typing, acceleration of engraftment, enhancement of the graft-versus-leukemia effect, and supportive care. Because improvements in transplantation tend to parallel those in chemotherapy, the indications for transplantation in newly diagnosed and relapsed patients should be reevaluated periodically. For example, the presence of Philadelphia chromosome is no longer a clear indication for transplantation with the advent of TKIs.

Dose Schedule

The biologically equivalent doses among the different formulations of corticosteroids, thiopurines, and asparaginase are not clear. Trials comparing such agents should be cautiously interpreted, taking into account the dose schedule used and the effect of variability in the pharmacokinetic profile and potency among the agents involved. Simple modification of the dose or schedule may result in significant differences in efficacy and toxicity. Also, when comparing regimens containing high-dose intravenous methotrexate, the dose schedule of leucovorin rescue should not be ignored because it plays a crucial role in modulating the activity and toxicity of methotrexate.

ACUTE LYMPHOBLASTIC LEUKEMIA RELAPSE

Most relapses occur during treatment or within the first 2 years after its completion, although relapses have been reported as late as 10 years after initial ALL diagnosis. The most common site of relapse is the BM.[27] Relapse in extramedullary sites, such as the CNS and testes, has decreased to less than 5% and 2% respectively. Leukemia relapse occasionally occurs at other sites, including the eye, ovary, uterus, bone, muscle, tonsil, kidney, mediastinum, pleura, and paranasal sinus. Extramedullary relapse in children with ALL frequently presents as an isolated clinical finding. However, in studies that included MRD assays, many extramedullary recurrences were associated with MRD in the BM. A small fraction of patients experience a recurrence of acute leukemia with an immunophenotype different from that determined at diagnosis. Some of the cases represent relapse of original leukemic clones with a shift in immunophenotype, but others are secondary malignancies caused by the mutagenic effects of leukemia treatment, especially from epipodophyllotoxin. Patients with isolated BM relapse generally fare worse than those with isolated extramedullary relapse.[28] Factors indicating an especially poor prognosis are a short initial remission and a T-cell immunophenotype. Other adverse factors include t(9;22). The presence of MRD at the end of second remission induction is also a strong adverse prognostic indicator. Although chemotherapy may secure a prolonged second remission in children with ALL who experience late relapse (defined as >6 months after cessation of therapy), allogeneic HSCT is the treatment of choice for patients who experience hematologic relapse during therapy or shortly thereafter and for those with T-cell ALL. Patients with late-onset isolated CNS relapse who had not received cranial irradiation as initial CNS-directed therapy have a very high remission retrieval rate, with a long-term prognosis approaching that of newly diagnosed patients in those who had a long initial remission before the CNS event.

Genome-wide studies using matched diagnosis and relapse samples from the same patients are exploring the genetic basis of relapse.

Although 90% of the patients exhibit differential gaining or losing genetic lesions from diagnosis to relapse, most relapse samples are clonally related to diagnosis samples. Relapse clones could be present as minor populations at diagnosis and selected during treatment to emerge as the predominant clone at relapse displaying alterations of genes that have been implicated in treatment resistance. Almost 20% of relapsed cases have sequence or deletion mutations of *CREBBP,* which impair histone acetylation and transcriptional regulation of CREBBP targets, suggesting that the mutations may confer drug resistance and raising the possibility of using drugs to reverse the aberrant epigenetic programs, such as histone deacetylase inhibitors.[29] The next generation of deep sequencing technologies promises to unravel many more if not the full repertoire of genetic alterations in leukemia. Parallel gene expression studies, which have identified a proliferative gene signature that emerges at relapse and consistent upregulation of genes such as *survivin,* provide attractive targets for novel therapeutic intervention.

SUPPORTIVE CARE

Stringent supportive care significantly contributes to a favorable ALL outcome and should be initiated at diagnosis because remission induction is associated with an increased risk from cardiovascular, metabolic, and infectious complications. All febrile patients with or without documented infection should be given broad-spectrum intravenous antibiotics until an infectious disease can be excluded. Rapid turnover of leukemia cells before and immediately after the initiation of chemotherapy leads to metabolic disturbances, including hyperkalemia, hyperuricemia, hyperphosphatemia, and hypocalcemia. Patients with high levels of uric acid are at risk for the development of acute renal failure secondary to uric acid deposition in the kidneys. All patients require intravenous hydration to prevent or treat hyperuricemia and hyperphosphatemia. Allopurinol, a xanthine oxidase inhibitor, can prevent uric acid formation. Rasburicase, a recombinant urate oxidase that breaks down uric acid to allantoin (a readily excretable metabolite with five- to 10-fold higher solubility than uric acid), is more effective than allopurinol but is associated with methemoglobinemia or hemolytic anemia in patients with glucose-6-phosphate dehydrogenase deficiency because hydrogen peroxide is a byproduct of the uric acid breakdown.[30] Phosphate binders should also be used to prevent or treat hyperphosphatemia. Transfusions should be administered slowly in patients with severe anemia to prevent congestive heart failure. In patients with extreme hyperleukocytosis, packed red blood cell transfusion should be delayed until after leukocyte count is decreased to prevent complications of leukostasis. All blood products should be irradiated in patients who are receiving immunosuppressive therapy to prevent GVHD. Patients should avoid foods that may be contaminated with pathogens and reduce salt intake, which could induce hypertension and resultant seizure in patients receiving glucocorticoids during induction. Adolescents, obese individuals, and individuals with Down syndrome are at increased risk of hyperglycemia and other complications. Prophylactic use of trimethoprim–sulfamethoxazole (or pentamidine or atovaquone in patients with poor tolerance to trimethoprim–sulfamethoxazole) successfully prevents *Pneumocystis jiroveci* (formerly *carinii*) pneumonia. Dental evaluation at diagnosis and meticulous oral hygiene during chemotherapy minimize the oral complications of leukemia and its treatment. It is important to distinguish between herpes simplex viral infection and chemotherapy-induced oral mucositis. Occasionally, patients have nausea and substantial pain on swallowing caused by esophageal herpes simplex viral infection, candidiasis, or both. Oral candidiasis occurs frequently, especially in young children. Azole compounds (e.g., fluconazole, itraconazole, ketoconazole) are frequently used to treat fungal infections. It should be recognized that they can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine. On the other hand, concomitant administration of anticonvulsants that induce cytochrome P450 enzymes (e.g., phenytoin, phenobarbital, carbamazepine) increases the systemic clearance of several antileukemic agents and may adversely affect treatment outcome. Anticonvulsants that are less likely to induce the activity of cytochrome P450 enzymes (e.g., Keppra) are recommended in patients receiving chemotherapy. Photosensitive skin rash can occur during antimetabolite therapy. The rashes are erythematous, maculopapular, similar to atopic eczema, and most prominent on the face. Topical administration of simple emollients or a weak steroid preparation and avoidance of external exposure to sunlight should improve the skin condition. Patients with Down syndrome tolerate methotrexate poorly; appropriate dose adjustment is indicated. During each clinic visit, a thorough review of all drugs should be undertaken because of potential adverse interactions among them. In fact, chemotherapy can also interact with various food (e.g., grapefruit) and supplements (e.g., St. John's wort, folic acid).[31]

Drug Interactions

We have not yet reached a full understanding of the contribution of genetic polymorphisms to interindividual differences in drug effects to allow us to translate this new knowledge into clinical practice. However, by simply avoiding drug interactions, one can prevent increased toxicity or reduced efficacy of chemotherapy. Phenytoin and phenobarbital induce the activity of cytochrome P450 enzymes, significantly increasing the systemic clearance of several antileukemic agents that may adversely affect treatment outcome. We substitute these anticonvulsants with gabapentin or Keppra in patients receiving antileukemic therapy. On the other hand, azole compounds (e.g., fluconazole, itraconazole, ketoconazole) can inhibit cytochrome P450 enzymes and increase the toxicities of various antileukemic agents, especially vincristine.

LATE EFFECTS OF TREATMENT

The most problematic late effects of contemporary ALL therapy include neuropsychological impairments, bone morbidity, and obesity. Although neuropsychologic deficits are well-recognized side effects of cranial irradiation, intrathecal and systemic chemotherapy (especially methotrexate) can also cause brain atrophy and spinal cord dysfunction and contribute to the development of neurocognitive toxicities. Severe CNS toxicity has been attributed to cranial irradiation at doses of 2400 cGy or higher, but lower doses have also been associated with long-term neuropsychological impairments, especially in younger children. Obesity, which is most prevalent among female survivors of childhood ALL, may be related to cranial radiation and corticosteroids. Osteopenia, fractures, and osteonecrosis have been observed in up to 30% of survivors of childhood ALL. Osteonecrosis, which can lead to significant pain, loss of function, and total joint replacement, has been reported in approximately 8% of children with ALL, with the highest frequency observed in those diagnosed in adolescence. Ovarian and testicular function are relatively unaffected by most antileukemic therapy. Offspring of patients successfully treated for childhood ALL are expected to be as normal as the general population. Second malignant neoplasms, including malignant gliomas, meningiomas, and AML, occur with increased frequency in patients treated on regimens that include irradiation, epipodophyllotoxins, or alkylating agents.

FUTURE DIRECTIONS

As the cure rate approaches 90%, treatment response assessed by MRD measurements of submicroscopic leukemia has emerged as a powerful and independent prognostic indicator for gauging the intensity of ALL therapy. Children at high risk of relapse may now benefit from early intensification of therapy. The next goal is to reduce the intensity of therapy in children at very low risk of relapse,

hence avoiding undue toxicity. The successful elimination of preventive cranial irradiation indicates that treatment reduction is feasible if done with caution and appropriate substitution with less toxic alternatives. Global genome analysis, in addition to refining leukemia classification, is helping identify potential molecular targets for therapy. Expanding the application of pharmacogenomics, a science that aims to define the genetic determinants of drug effects, will allow further personalized therapy in the future.

ACUTE LYMPHOBLASTIC LEUKEMIA IN ADULTS

Nitin Jain, Sandeep Gurbuxani, Charles Rhee, and Wendy Stock

Acute lymphoblastic leukemia (ALL) is a heterogeneous group of diseases characterized by clonal proliferation of lymphoid progenitors (lymphoblasts). Improved diagnostic tools permit accurate and prompt diagnosis and aid in evaluation of minimal residual disease (MRD). There have been significant advances in the past decade toward understanding disease pathogenesis, refinement of prognostic groups, and the development of novel therapies targeted toward specific disease subsets. These risk-adapted therapies are transforming the treatment strategies for adults with ALL and are beginning to result in significant improvements in survival.

EPIDEMIOLOGY

It is estimated that in the year 2012, 6050 men and women would be diagnosed with ALL in the United States. ALL is primarily a cancer of childhood; the peak incidence (7.7 in 100,000) occurs between the ages of 1 and 4 years, and approximately 60% of the patients are diagnosed before the age of 20 years. The incidence of ALL begins to decline with increasing age after the first decade of life. A second upward trend starts to emerge in the sixth decade of life, and a much smaller peak is seen in patients older than 85 years of age (1.8 in 100,000). Men have a slightly higher incidence of ALL than women (male-to-female ratio, 1.4 to 1). The overall age-adjusted rate of ALL has increased from 0.93 in 100,000 in the year 1975 to 1.47 in 100,000 in the year 2008. Similar increases in the incidence of ALL have also been reported in Scandinavia, the United Kingdom, and Italy. Although most investigators agree that this increase in the incidence is beyond what might be expected from better reporting, the actual cause(s) of this increased incidence remains largely speculative.

ETIOLOGY

A small minority of ALL cases (<5%) are associated with predisposing inherited syndromes such as Down syndrome, Bloom syndrome, ataxia telangiectasia, and Nijmegen breakage syndrome. However, the underlying etiology is not known in most cases. Although parental tobacco or alcohol use, exposure to pesticides or solvents, and cigarette smoking have all been implicated, only ionizing radiation has been significantly linked to increased risk of developing ALL. The vast majority of literature that attempts to identify causative agents for ALL is at best correlative; most of it borders on pure speculation and conjecture. Only recently has it been appreciated that the interaction between genetic predisposition and environmental factors involved in leukemogenesis is complex and may be different for different subtypes of ALL. Epidemiologic studies designed to identify environmental agents involved in leukemogenesis will therefore have to take into account the biologic subsets defined by morphology, immunophenotype, karyotype, and the molecular abnormalities and consider the possibility that for each of these subtypes, the causative agent may well be different. To adequately investigate these issues, future studies will require collaborative efforts studying large patient populations.

Despite the limitations described, it is relevant to review some of the recent advances in our understanding of the etiology of ALL. Greaves and colleagues have used DNA obtained from neonatal blood spots to demonstrate that ALL-associated chromosomal translocations (and hence a preleukemic clone) can be demonstrated in neonatal blood spots that are acquired in utero. Furthermore, these are present at 100-fold higher rate than the incidence of leukemia. These investigators hypothesize that overt leukemia evolves as a consequence of an abnormal lymphoid proliferation that occurs in response to exposure to an as yet unidentified infectious agent(s). Supporting this hypothesis are data that suggest that day care attendance associated with early exposure to common infectious agents is associated with a lower incidence of ALL. Similarly, industrialization associated with improved socioeconomic status and exposure to common infectious agents later in life has been postulated to result in abnormal and excessive lymphoid proliferation and leukemic transformation. Finally, an infectious etiology can also be evoked to explain leukemic clusters that occur when a previously unexposed community is exposed to infectious agents brought into the community by a large influx of residents as happens during urbanization of rural communities. However, it needs to be reiterated that all of these studies are at best correlative and not supported by direct experimental evidence. Furthermore, the infectious or environmental agent(s) responsible for this abnormal lymphoid proliferation remains elusive.

APPROACH TO DIAGNOSIS

While evaluation of morphology and immunophenotype are sufficient for making the diagnosis, current risk stratification relies on additional cytogenetic and molecular genetic information. Data from these tests is therefore an important adjunct to the initial diagnostic work up.

Initial laboratory evaluation starts with a complete blood count (CBC) and morphologic evaluation of a Giemsa-stained peripheral blood smear. An abnormality of at least one of the CBC parameters is detected in more than 90% of ALL patients at the time of diagnosis. Anemia and thrombocytopenia are common. The anemia is usually a normochromic, normocytic anemia accompanied by reticulocytopenia. The hemoglobin levels range from 30 to 174 g/L, and almost 50% of the patients have hemoglobin levels below 100 g/L. The median platelet count at presentation is approximately 55 to 60×10^9/L, and almost 60% to 70% of patients have platelet counts below 100×10^9/L. Although the total white blood cell (WBC) count may be low, normal or elevated, neutropenia is commonly present. In a Cancer and Leukemia Group B (CALGB) study, the median WBC count at presentation was 19.3×10^9/L. Almost one-third of the patients are likely to present with WBC count greater than 30×10^9/L. Blasts account for a variable proportion of the circulating WBCs, and the percent blast population can range from 0% to 100%. A leukoerythroblastic picture can sometimes be seen. In an extreme form, immature myeloid precursors and myeloblasts constitute the vast majority of cells in the peripheral blood. This should be kept in mind when attempting to make a diagnosis exclusively from

peripheral blood. Eosinophilia as a presentation of ALL is extremely uncommon and is seen in association with specific chromosomal abnormalities, including t(5;14)(q31;q32) or, even less frequently, with 8p11-associated ALL. Eosinophilia associated with t(5;14) is reactive and due to overexpression of interleukin-3 (IL-3) on chromosome 5 driven by the IgH promoter on chromosome 14. The eosinophilia can be extremely pronounced and mask the blast population in this subset of patients.

Several metabolic abnormalities are present at the time of diagnosis and frequently reflect tumor burden. For example, lactate dehydrogenase (LDH) levels are frequently elevated, and almost 50% of the patients have levels between 300 and 1000 U/L. Elevated serum levels of calcium, potassium, and phosphorous have been noted. More importantly, elevated serum uric acid levels are frequently present and reflect tumor burden. Hyperuricemia needs to be carefully monitored and aggressively corrected to avoid renal failure, especially at the time of starting induction therapy.

MORPHOLOGY

Romanowsky-based stains such as Wright's Giemsa and Giemsa provide the greatest cytoplasmic detail for evaluation of cytomorphology of the cells in the peripheral blood smear, bone marrow (BM) aspirate smear, and touch imprints (Fig. 65-1). Most frequently, lymphoblasts are small to intermediate in size and have scant, agranular cytoplasm. B lymphoblasts are morphologically indistinguishable from T lymphoblasts, and this distinction relies on immunophenotyping. The nuclei are usually round, with uniformly dispersed "smudgy" chromatin and inconspicuous nucleoli (see Fig. 65-1, *C*). However, variations in morphology are common, and larger cells with abundant bluish gray cytoplasm, larger, somewhat irregular nuclei, and variably prominent nucleoli can be frequently seen (see Fig. 65-1, *D*). Even though the nuclear chromatin of these cells can be fine, it is never as finely dispersed as in a myeloblast. At the other end of morphologic spectrum are smaller cells with uniformly condensed, mature lymphocyte-like chromatin (see Fig. 65-1, *E*), and distinction from mature B-cell malignancies relies on immunophenotyping. Coarse azurophilic granules (see Fig. 65-1, *F*) can be seen in a subset of blasts in 5% to 8% of childhood ALLs and even more frequently in adult ALL patients. These have been reported in association with Philadelphia chromosome–positive (Ph^+) ALL and in ALL in Down syndrome patients. The granules are coarser than the granules seen in myeloblasts and are invariably myeloperoxidase negative (see later discussion of cytochemistry). Morphologic distinction between L1 and L2 category recommended in the French–American–British (FAB) classification has proven to be poorly reproducible and of little prognostic value. It has been abandoned in the current World Health Organization (WHO) classification.

Cytoplasmic vacuolation (see Fig. 65-1, *H*) can be seen in as many as 28% of childhood ALL patients. These lymphoblasts can be distinguished from leukemic presentation of Burkitt lymphoma (BL; see later discussion) based on other morphologic features such as a smaller cell size, lack of deep blue cytoplasm, and less coarse chromatin. However, when morphology is confounding, the distinction relies on immunophenotyping of the malignant cells. In contrast to BL cells, ALL blasts are precursor B cells that express terminal deoxynucleotidyl transferase (TdT) and lack surface immunoglobulin expression (see later discussion).

The trephine biopsy sections show hypercellular BM (Fig. 65-2). The sections are evaluated after staining with hematoxylin and eosin. The BM is usually packed with a relatively uniform population of

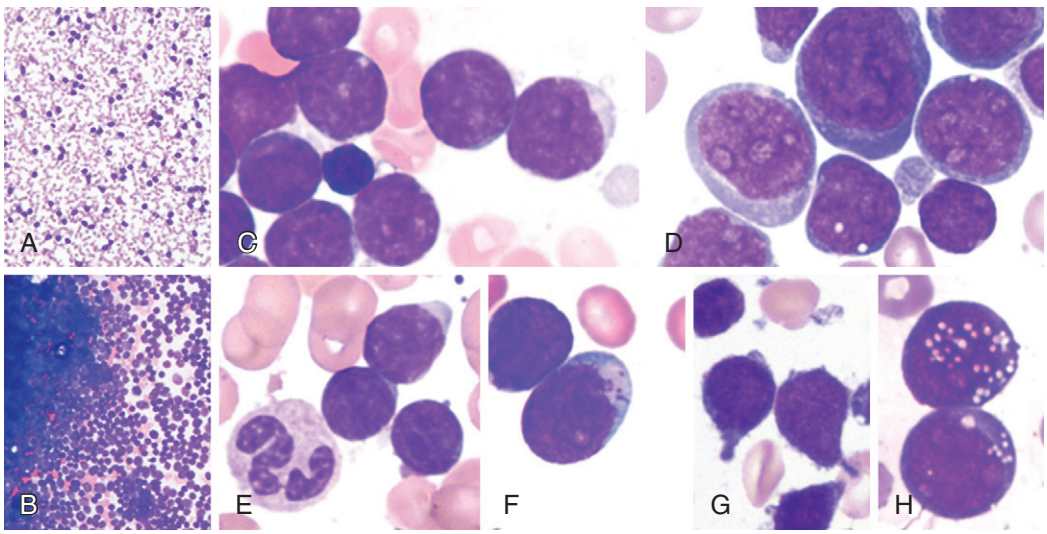

Figure 65-1 MORPHOLOGIC FEATURES OF ACUTE LYMPHOBLASTIC LEUKEMIA (ALL) IN THE BLOOD AND BONE MARROW (BM) ASPIRATE. In ALL, the peripheral blood count can be low, normal or high, although frequently it is high and composed of mostly blasts **(A).** A similar range in cellularity is true regarding the BM **(B).** Typically, lymphoblasts are small to intermediate in size and have round nuclei with dispersed chromatin and indistinct nucleoli. They have scant pale blue cytoplasm **(C).** A small lymphocyte (**C,** *middle, left*) is useful for comparison. In many cases, the lymphoblasts are monotonous, but in some cases, the lymphoblast morphology is varied with some large cells, some cells with abundant cytoplasm, and other cells with prominent nucleoli **(D).** In the older French–American–British (FAB) classification, these two patterns were referred to as ALL-L1 and ALL-L2, respectively, although they have been shown not to have any clinical significance. Other cytologic variants of lymphoblasts are shown in **E** to **H.** These include lymphocyte-like blasts **(E),** blasts with azurophilic granules **(F),** blasts with "hand-mirror" morphology **(G),** and blasts with vacuoles **(H).** The small lymphocyte-like blasts can be difficult to distinguish from chronic lymphocytic leukemia cells in the blood, making flow immunophenotyping important in the distinction. Lymphoblasts with granules can be misleading as they can be mistaken for myeloblast or monoblasts. The hand-mirror cells appear to be an artifact because they can be seen only focally on a smear. Vacuoles in the blasts can make the blasts difficult to distinguish from Burkitt cells (see also Fig. 65-7). However, flow cytometry can easily distinguish the immature ALL blasts from the mature B cells seen in a leukemic presentation of Burkitt lymphoma.

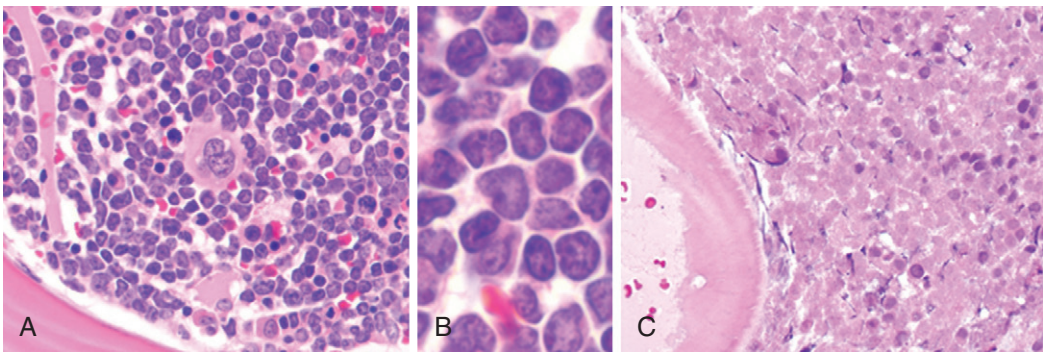

Figure 65-2 MORPHOLOGIC FEATURES OF ACUTE LYMPHOBLASTIC LEUKEMIA (ALL) IN THE BONE MARROW (BM) BIOPSY. The findings in the BM biopsy in ALL are varied, but frequently the biopsy is 100% cellular and packed with blasts **(A).** Sometimes there is some residual hematopoiesis with sparing of megakaryocytes as shown. A high power of the lymphoblasts is shown in **B** illustrating the fine, dispersed, and "blastic" chromatin pattern of the cells. Sometim**es** the BM can be hypocellular (not shown); however, the majority of the cells in such cases are blasts. Sometimes there is necrosis **(C).** The necrotic cells are referred to as "ghost" cells. They may retain some of their antigen expression as identified by immunostains; however, if the entire biopsy shows necrosis, a diagnosis should be made from the findings in the blood or a repeat BM may be necessary. Other tumors can present with BM necrosis.

small round blasts with round to oval nuclei. Less frequently, the blasts can be more pleomorphic with indented, convoluted, and variably sized nuclei. The chromatin is described as being finely dispersed or stippled and the nucleoli are usually not conspicuous. Brisk mitotic activity is almost always present. The effacement of the BM space is almost complete and uniform at the time of initial presentation. Minimal residual hematopoiesis is present; in most instances this is represented by a few megakaryocytes and some erythropoiesis. Normocellular or even hypocellular BMs at presentation have been described but are uncommon. Rarely, the initial presentation of ALL can be with an aplastic or markedly hypocellular BM. Making the diagnosis in this hypocellular context can be particularly challenging because of a paucity of material available for supporting studies such as cytogenetics and immunophenotyping.

Bone marrow biopsy can show partial or complete necrosis (see Fig. 65-2, *C*). When extensive necrosis is present, making a diagnosis can be challenging or almost impossible. A repeat BM biopsy should be attempted and will usually provide diagnostic material. Some increase in reticulin fibrosis is present in 60% to 70% of ALL patients. When fibrosis is extensive, an aspirate cannot be obtained, limiting material available for ancillary studies such as flow cytometry and cytogenetics. For these patients, the immunophenotyping can be performed by immunoperoxidase immunohistochemistry on the bone core biopsy. A second core can be obtained and submitted without fixation to the cytogenetic laboratory; evaluation can be performed from cells obtained from the disaggregation of the core.

Organs other than the BM can be frequently involved. Extramedullary or lymphomatous presentation is more common with T–acute lymphoblastic leukemia (T-ALL) than B–acute lymphoblastic leukemia (B-ALL) (described later in Clinical Manifestations). The cytomorphology of the malignant cells in extramedullary disease is similar to that described in the bone core biopsy. Lymph node involvement is usually diffuse but can be partial with sparing of the follicles.

CYTOCHEMISTRY

The use of cytochemistry to assign lineage has been largely replaced by flow cytometry evaluation of the leukemic blast immunophenotype. However, when available, the myeloperoxidase reaction (Fig. 65-3, *A* and *B*) permits a rapid distinction from acute myeloid leukemia (AML). The reaction detects the myeloperoxidase enzyme in the primary granules of myeloblasts and is specific for the myeloid lineage. An acute leukemia in which 3% or more of the cells are myeloperoxidase positive is considered myeloid. There is excellent concordance between the myeloperoxidase reaction detected by cytochemistry and the myeloperoxidase molecule detected by flow cytometry. A blocklike positivity has been described with the periodic acid-Schiff (PAS) reaction that detects glycogen in almost 50% of ALL cases.

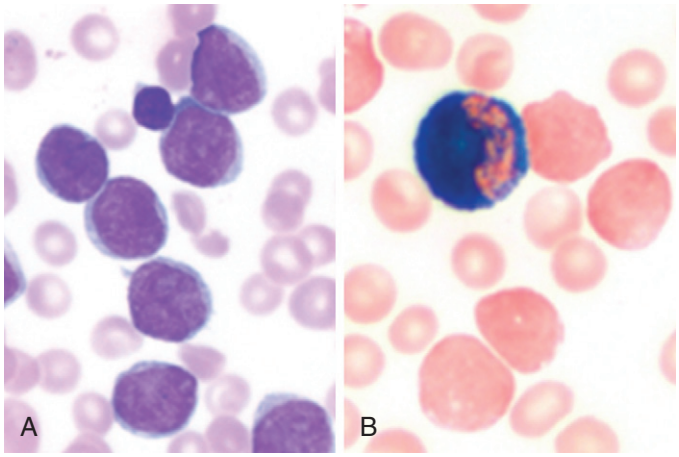

Figure 65-3 CYTOCHEMISTRY IN ACUTE LYMPHOBLASTIC LEUKEMIA. The blasts in acute lymphoblastic leukemia **(A)** are always myeloperoxidase reaction negative. **B,** Compare the blasts with a single positively reactive granulocyte with a black–blue reaction product. Evaluating for nonspecific esterase reactivity (α-naphthyl acetate esterase, or alpha naphthyl butyrate esterase) might also be performed when the blasts are difficult to distinguish from monoblasts.

IMMUNOPHENOTYPE

Based on large cooperative group studies in Europe and the United States, the incidence of B-ALL ranges from 75% to 80% and T-ALL from 15% to 25%. B lymphoblasts cannot be distinguished from T lymphoblasts by morphology. Extensive immunophenotypic characterization is therefore required for the appropriate classification of ALL and indeed distinction from certain subtypes of AML. When adequate material is available, immunophenotyping should be performed using multicolor flow cytometry so that multiple antigens can be detected simultaneously on the lymphoblasts (Fig. 65-4). When interpreting the immunophenotypic data, it is important to remember that no single antigen is specific for any given lineage and multiple

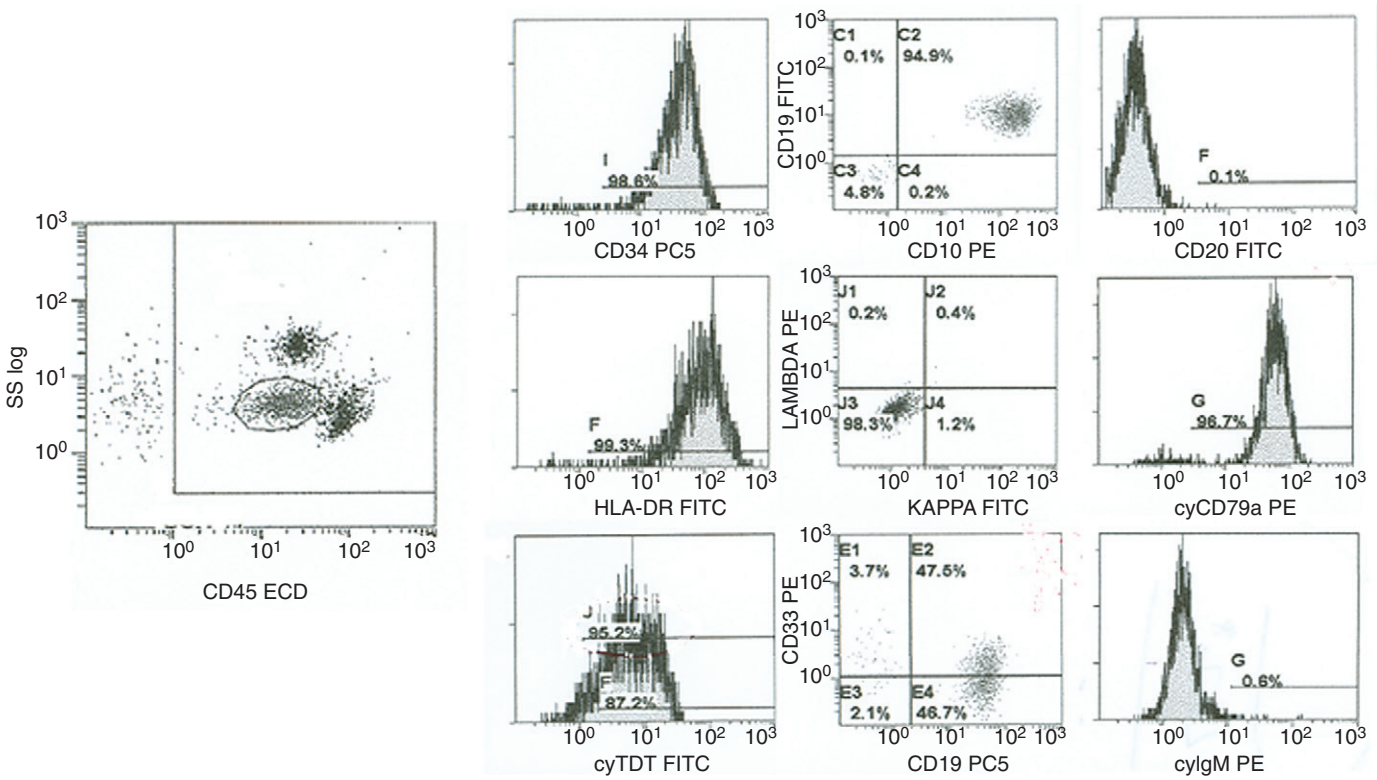

Figure 65-4 AN EXAMPLE OF FLOW CYTOMETRIC EVALUATION IN A CASE OF B–ACUTE LYMPHOBLASTIC LEUKEMIA (B-ALL). Selected histograms from a panel of markers used in the evaluation of ALL by flow cytometry are illustrated. The blasts are first identified by weak CD45 expression and low side scatter *(left histogram, circled population).* This is a useful gating strategy because it allows for an easy identification of the blast population and its separation from lymphocytes (with bright CD45) and nucleated red blood cells (with absent CD45 expression). Because no single antigen is specific for a lineage, multiple antigens are evaluated using multicolor flow cytometry. The phenotype illustrated is that of a common precursor B-ALL. In this case, the blasts are $CD34^+$, $HLA\text{-}DR^+$, TdT^+, $CD19^+$, $CD10^+$, $CD20^-$, $cyCD79a^+$, κ^-, λ^-, and $cyIgM^-$. There is weak and partial expression of the myeloid marker CD33.

antigens need to be evaluated to establish the correct diagnosis. The panel of antibodies used for flow cytometry of a new leukemia and the pattern of expression seen in B- and T-ALL are shown in Table 65-1. In addition, the combination of markers expressed on the B or T lymphoblasts can be reflective of the stage of development at which the transformation happened (Table 65-2). Of note, expression of myeloid antigens is seen frequently in B- and T-ALL, as is the expression of T-cell antigens in B-ALL and B-cell antigens in T-ALL. Expression of individual myeloid antigens should not be a deterrent to making the diagnosis of ALL. The criteria for diagnosis acute leukemias of ambiguous lineage, which would include mixed phenotype acute leukemia, have been extensively revised in the current WHO classification.

GENETICS

Chromosomal abnormalities can be detected in almost 80% of B-ALLs and 70% of T-ALLs. Cytogenetic classification remains the single most important prognostic factor in both pediatric and adult ALL. Numerical abnormalities as well as structural abnormalities that disrupt the function of transcription factors involved in hematopoietic development and differentiation are common. These genetic abnormalities define the biology of the disease and have an impact on treatment outcome. In addition, specific cytogenetic or molecular abnormalities are associated with unique phenotypic characteristics and are amenable to targeted therapy. Although Ph^+ ALL is the first subset of ALL to use a molecularly targeted tyrosine kinase inhibitor (TKI) therapy as frontline treatment, it is likely that more genetically defined entities will be targeted for specific therapy. This has been recognized in the 2008 WHO classification with a specific discussion on lymphoblastic leukemia/lymphoma with recurrent cytogenetic abnormalities (Table 65-3). Although the discussion in the current WHO classification is neither comprehensive nor complete, it does establish a framework for future discussion for appropriate classification of ALL. Association with distinct phenotypic properties or clinical behavior determines inclusion of specific entities in the 2008 classification.

Hyperdiploidy defined by the presence of more than 50 chromosomes is seen in almost 25% of pediatric patients and 4% to 5% of adult ALL patients. In addition to routine karyotyping or fluorescent in situ hybridization (FISH) analysis, hyperdiploid DNA content can be determined by flow cytometry using DNA binding fluorescent dyes and corresponds to a DNA content between 1.16 and 1.6. However, some studies have demonstrated that hyperdiploidy resulting from duplication of specific chromosomes (4, 10, and 17) is a better indicator of a favorable prognosis than the actual ploidy or the DNA content. In contrast, patients with a hypodiploid karyotype with a chromosome number below 46 is associated with an adverse prognosis. Another abnormality seen commonly in the pediatric age group but extremely rarely in the adult age group is a cryptic translocation, the t(12;21)(p13;q22)*(ETV6-RUNX1).* When present, it is associated with a favorable prognosis. Leukemias that harbor rearrangements of the *MLL* (mixed-lineage leukemia) gene at chromosome 11q23, most notably t(4;11)(q21;q23), present with high WBC counts and frequent central nervous system (CNS) involvement and are associated with poor clinical outcomes. Ph^+ ALL associated with t(9;22)(q34;q11.2) account for 25% of adult ALL. The presence of this translocation was invariably associated with a poor outcome before inclusion of TKIs into frontline treatment.

More recently, submicroscopic genomic alterations have been detected that have significant impact on the biology of ALL. These involve transcription factors such as *IKZF1* (Ikaros), *EBF,* and *PAX5.* Additionally, intrachromosomal amplification of chromosome 21

§Rarely present.
‖Only marker considered lineage specific.
¶Frequently coexpressed.

(iAMP21) that results in multiple copies of *RUNX1* has also been described in 2% of B-ALL patients and appears to be associated with a dismal outcome. The role of these transcription factors in B-cell development and the biology of B-ALL are discussed in greater detail in Chapter 63. More recently, *CRLF2* overexpression has been identified in approximately 14% of high-risk ALL patients. The overexpression is driven by either translocation of the *IGH2* gene on chromosome 14q32 to the *CRLF2* on Xp22.3/Yp11.3 (pseudoautosomal region 1) or by a 320-kb interstitial deletion centromeric of *CRLF2* resulting in *P2RY8-CRLF2* fusion. *CRLF2* overexpression is frequently associated with activating mutations of *JAK1* or *JAK2* and deletion or mutations of *IKZF1*. In addition, patients with *CRLF2* overexpression have extremely poor survival despite treatment with intensive chemotherapy. Notably, flow cytometry can be used to detect *CRLF2*

Table 65-2 Immunophenotypes of B- and T-Lymphocyte Progenitors

Table 65-3 Significant Features of B-Acute Lymphoblastic Leukemia With Recurrent Cytogenetic Abnormalities in the 2008 World Health Organization Classification

Cytogenetic Abnormality	Phenotype	Clinical Correlates	Incidence #
t(9;22)(q33;q11.2)	$CD19^+$, $CD10^+$, $CD25^+$; frequent expression of myeloid antigens	Seen more frequently in adults; traditionally associated with extremely poor outcome; improved early event-free survival with targeted therapy	19% of all adult ALL patients; incidence increases with age
t(v;11q23) Common fusion partners include AF4 (4q21) and ENL (19p13)	$CD19^+$, $CD10^-$; aberrant expression of myeloid antigen CD15	Frequent presentation with high WBC count, CNS involvement	9% of Ph-negative adult ALL
t(12;21)(p13;q22) Cryptic translocation; requires FISH	$CD19^+CD10^+$; aberrant expression of myeloid antigen CD13	Sensitive disease with favorable outcome on standard therapy	2%-3% of Ph-negative adult ALL
Hyperdiploidy Chromosome number >50, <66 Extra copies of nonrandom chromosomes, most frequently 21,X,14, and 4	$CD19^+$, $CD10^+$; no distinctive phenotype	Sensitive disease with favorable outcome on standard therapy	10% of Ph-negative adult ALL
Hypodiploidy Chromosome number <46	$CD19^+$, $CD10^+$; no distinctive phenotype	Poor prognosis	4% of Ph-negative adult ALL
t(5;14)(q31;q32)	$CD19^+$, $CD10^+$; no distinctive phenotype	Reactive eosinophilia driven by IL-3 overexpression driven by the translocation; blasts may be <20% in the BM and undetectable in peripheral blood	Rare in adults
t(1;19)(q23;p13.3)	$CD19^+$, $CD10^+$; cytoplasmic μ^+	No significant association with response to therapy on current protocols	3% of Ph-negative adult ALL

overexpression in the clinical laboratory. As we acquire a better understanding of the effect of these genetic alterations on the biology of ALL, they are likely to have an impact on how we risk stratify ALL patients and indeed exploit these aberrations for targeted therapy.

Similar to B-ALL, translocations involving transcription factors are common in T-ALL. The most commonly involved genes include *HOX11* and *HOX11L2*. Other genes that have been described to be involved in T-ALL are *MYC, TAL1, LMO2,* and *LYL1*. Similar to t(12;21), translocations involving the *TAL1* gene are cryptic and require detection by molecular techniques. Activating mutations of the *NOTCH1* gene are detected in almost 50% of ALL patients. Although activating mutations of *NOTCH1* appear to be associated with disease pathogenesis, they do not appear to be associated with an adverse prognosis in the majority of studies; in fact, some pediatric studies suggest that NOTCH1-mutated T-ALL may have a relatively favorable response to current treatment regimens. Deletions of the *CDKN2A* gene on chromosome 9p are also particularly frequent as are mutations in the *FBXW7* gene, but neither has clear prognostic significance as single abnormalities. The significance of these mutations remains an area of active research.

CLINICAL MANIFESTATIONS

The clinical presentation of ALL encompasses a wide spectrum of symptoms that correlate with the degree of BM involvement and the resultant cytopenias, as well as the leukemic cell burden. Typical symptoms include fatigue, anorexia, night sweats, pallor, shortness of breath, bone pain, fever, and bleeding diathesis. Involvement of extramedullary sites may present with lymphadenopathy, hepatomegaly, or splenomegaly. Less commonly, ALL can involve the CNS, leading to headache, vomiting, lethargy, and cranial nerve palsies. Other extramedullary sites of involvement include the testis, tonsils, adenoids, breast, and gastrointestinal tract. Precursor T-cell ALL often presents with a large mediastinal mass with associated respiratory distress or possible signs of superior vena cava syndrome. Burkitt leukemia/lymphoma is frequently associated with CNS involvement and bulky adenopathy.

CLINICAL AND LABORATORY EVALUATION

The initial workup for patients with suspected ALL is detailed in Table 65-4. All patients should undergo a detailed history and physical examination. Family history should be ascertained. Laboratory evaluation should include CBC with differential; comprehensive metabolic panel, including liver function tests, LDH, and uric acid. Coagulation profile should also be obtained, although coagulation parameters are frequently normal at diagnosis. Human leukocyte antigen (HLA) testing should be obtained for patients who are potential candidates for allogeneic stem cell transplantation (aSCT).

All patients should undergo BM aspiration and biopsy for confirmation of diagnosis and for cytogenetic and molecular genetic evaluation. It is particularly important to send an aspirate (or peripheral blood if lymphoblasts are present) to the molecular oncology diagnostic laboratory to evaluate for the presence of the *BCR-ABL* fusion transcript using reverse transcriptase polymerase chain reaction (RT-PCR) because these patients will receive frontline therapy that includes a TKI.

A lumbar puncture should be performed at diagnosis to determine CNS involvement. In the event of increased risk of bleeding caused by severe thrombocytopenia or risk of cerebrospinal fluid contamination caused by high peripheral blood blasts, lumbar puncture should be performed by an experienced operator. It is prudent to administer intrathecal chemotherapy at the time of the diagnostic lumbar puncture after obtaining the necessary samples.

Table 65-4 Initial Evaluation of a Patient With Acute Lymphoblastic Leukemia

- Complete history (including family history)
- Physical examination
- CBC with differential
- Comprehensive metabolic profile, including LFTs
- LDH, uric acid
- Coagulation profile
- BM aspiration and biopsy (morphology, immunohistochemistry, flow cytometry, molecular and cytogenetic analysis)
- HLA typing of the patient (if a potential aSCT candidate)
- Lumbar puncture
- Chest radiography or CT imaging of the chest

aSCT, Allogeneic stem cell transplantation; *BM,* bone marrow; *CBC,* complete blood count; *CT,* computed tomography; *HLA,* human leukocyte antigen; *LDH,* lactate dehydrogenase; *LFT,* liver function test.

DIFFERENTIAL DIAGNOSIS

Acute lymphoblastic leukemia blasts can be easily distinguished from the reactive lymphocytes seen in viral infections because of the precursor phenotype of these cells. Low to weak expression of CD45 and expression of one or more precursor antigens such as TdT or CD34 is useful. In addition, precursor T-ALL cells express only cytoplasmic CD3 and no surface CD3, and B-ALLs frequently lack expression of CD20 while being CD19 positive. As previously mentioned, ALL cells can have some cytoplasmic vacuolation and need to be distinguished from leukemic presentation of BL. Unlike ALL, BL cells are mature B cells with bright surface immunoglobulin expression, very strong CD20 expression, and no expression of CD34. Diagnosis of BL is confirmed by the presence of an *MYC* translocation using FISH or cytogenetics. Other entities that require distinction from ALL depend on the age of presentation. In the pediatric age group, ALL blasts need to be distinguished from hematogones. Hematogones are normal B-cell precursors present within the BM. These are more abundant in childhood and decrease with increasing age. Hematogones may also be increased during hematopoietic regeneration, particularly after chemotherapy or BM engraftment after stem cell transplant. Hematogones possess a distinct pattern of antigen expression that recapitulates progressive B-cell maturation. This is reflected in progressive loss of antigens such as CD34, TdT, and CD10 and acquisition of CD20 and surface immunoglobulin expression (Fig. 65-5). Other diseases that need to be morphologically distinguished from ALL include small blue cell tumors, including Ewing sarcoma, neuroblastoma, and medulloblastoma. Ancillary studies, including immunophenotyping and cytogenetics, are helpful in making the distinction. In older adults, entities that can morphologically mimic ALL include blastoid mantle cell lymphoma, chronic lymphocytic leukemia, and prolymphocytic leukemia. These latter are all mature B-cell malignancies that can be distinguished from ALL based on the mature B-cell phenotype, including consistent expression of CD20 and surface immunoglobulins.

PROGNOSIS

Prognostication based on clinical and biologic risk factors has been useful in making informed decisions about postremission treatment options. Established risk factor for a poor prognosis with current chemotherapeutic approaches include age older than 60 years, elevated WBC count at diagnosis (>30,000/μL for B-cell ALL; >100,000/μL for T-cell ALL), pro–B cell or early T-cell immunophenotype, and cytogenetics (t(4;11)(q21;q23) and other *MLL* rearrangements, hypodiploidy, or a complex karyotype). The presence of the Philadelphia chromosome, t(9;22)(q34;q11.2) resulting in the *BCR-ABL* fusion gene was previously associated with very poor treatment outcomes. Recent addition of ABL kinase inhibitors

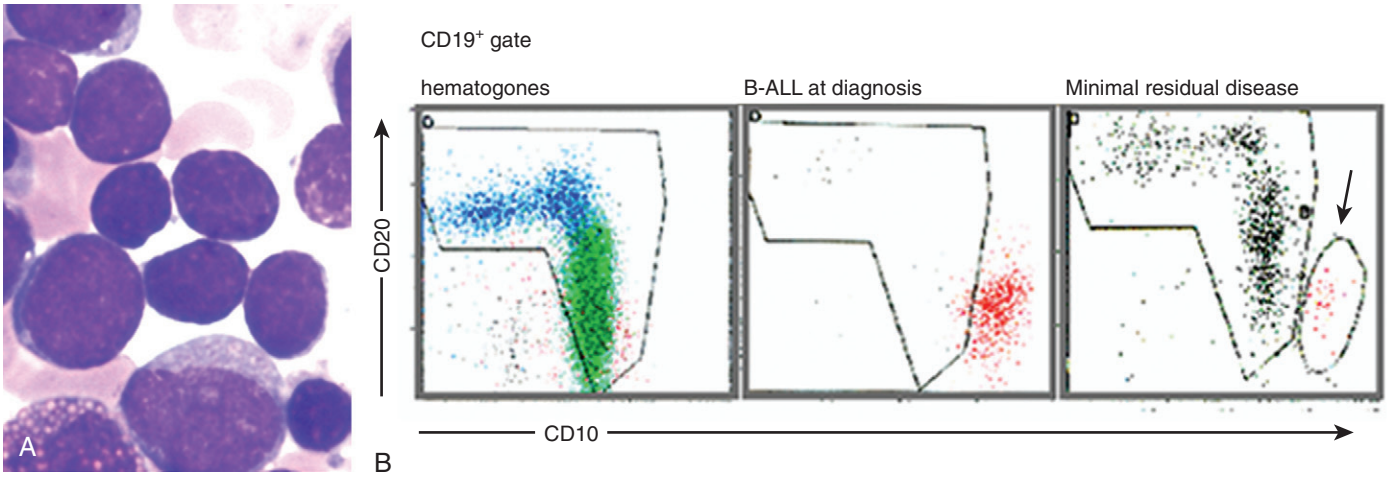

Figure 65-5 HEMATOGONES AND FLOW CYTOMETRIC EVALUATION OF MINIMAL RESIDUAL DISEASE (MRD). Hematogones are nonmalignant immature precursor B cells that are present in the bone marrow (BM). They are more commonly seen in pediatric patients but can be seen in adults during BM regeneration or associated with other conditions. **A,** They can be difficult to distinguish morphologically from malignant lymphoblasts because the cytologic features overlap significantly. **B,** Unlike malignant lymphoblasts, hematogones exhibit a spectrum of maturation that can be seen, for example, by analyzing CD10 and CD20 expression on $CD19^+$ cells *(left histogram).* Hematogones are $CD10^+$, but as CD20 is expressed, CD10 is diminished. Lymphoblasts, on the other hand, frequently exhibit maturation arrest and over- or underexpression of markers. They can also exhibit aberrant markers. In the *middle histogram,* the B lymphoblasts from the initial diagnosis specimen can be seen *(red)*, and the CD10 and CD20 expression is outside the normal hematogone range with overexpression of CD10 and absence of CD20. This pattern can be used to identify MRD *(right histogram)* and distinguish regenerative hematogones *(black)* from residual or recurrent blasts *(red)* after therapy. Multiple markers and parameters are usually used to study posttherapy specimens in this way.

(molecularly targeted therapy), discussed in detail later, has improved the prognosis for these patients. Time to achievement of complete remission (CR) longer than 4 weeks has also been associated with a poor clinical outcome (Table 65-5).

Although different study groups have used slightly different variations of these risk factors, the presence of any one of the following is generally accepted as high risk (HR): high WBC count at diagnosis (>30,000/μL in B-cell ALL or >100,000/μL in T-cell ALL); cytogenetic abnormalities [hypodiploidy, t(4;11), t(9;22)]; age older than 60 years; pro–B cell phenotype; and time to remission longer than 4 weeks. All other patients are considered standard risk (SR).

Nevertheless, despite being labeled as SR, up to 40% to 50% of these adults eventually relapse. Thus, there is a need for refinement of prognostic markers for ALL patients. Recently, an early T-cell phenotype, the expression of $CD20^+$ and several recently described genetic mutations (*IKAROS, CRLF2,* and *JAK2;* and reviewed earlier in this chapter) have been identified as being associated with adverse outcomes from retrospective analyses.

MINIMAL RESIDUAL DISEASE

The identification and measurement of MRD (subclinical disease) using leukemia clone-specific quantitative PCR and flow cytometry is an independent prognostic that is now being used to guide postremission therapies in many pediatric and some adult ALL treatment studies. In general, these techniques have not yet been widely standardized; however, the majority of studies demonstrate that MRD detection during early postremission therapy is a reliable and independent predictor of relapse. The optimal time point for outcome prognostication based on MRD measurements varies from study to study; undoubtedly, some of this variability is the result of differences in the PCR technique used, the sensitivity of detection of MRD of the individual assay, and the treatment intensity and the population being studied. Nevertheless, the majority of studies indicate that MRD detection anywhere from 4 to 20 weeks from initiation of treatment is highly predictive of relapse. Thus current studies are using novel approaches to try to eradicate MRD during early remission or stratifying MRD-positive patients to early intensification with aSCT to try to improve survival for these patients at very high risk for relapse.

Table 65-5 Markers for Poor Prognosis in Adult Acute Lymphoblastic Leukemia

Established Risk Factors	
Age	>60 years
Presenting WBC count	>30,000/μL (B-cell ALL); >100,000/μL (T-cell AL)
Immunophenotype	Pro–B cell; early T-cell
Cytogenetics	t(4;11)(q21;q23) and other *MLL* rearrangements t(9;22)(q34;q11.2) - Philadelphia chromosome Hypodiploidy (<44 chromosomes) Complex (>five abnormalities)

*Different studies have used different time points for MRD assessment.

TREATMENT OF ACUTE LYMPHOBLASTIC LEUKEMIA

Combination chemotherapy is the cornerstone of ALL management. In the 1960s, investigators at the National Institutes of Health designed multidrug chemotherapy regimens given over many different courses for pediatric ALL patients. A similar approach was then introduced for adults with ALL. The Berlin-Frankfurt-Muenster (BFM) group in the 1980s conducted pioneering studies and showed

that an intensive multidrug induction and consolidation chemotherapy followed by delayed intensification led to improvement in survival in the majority of children. These regimens combine drugs with varying mechanisms of action at different doses, often in complex schedules, which have largely evolved empirically. Only a few of these drugs have been tested individually in randomized clinical trials in adults with ALL; therefore, the relative contribution of each of the drugs in a multidrug regimen to the overall outcome is difficult to assess. Because there is an increased propensity for CNS involvement in ALL patients, all treatment regimens must also include CNS prophylaxis with intrathecal chemotherapy with or without cranial radiation.

The therapy for ALL is typically divided into three phases: (1) the remission induction phase, (2) remission consolidation or intensification, and (3) the maintenance (or continuation) phase. The remission induction and consolidation phases typically involve blocks of monthly treatment for 6 to 8 months followed by long-term maintenance, which is given for up to 3 years; thus, the treatment of ALL is long and challenging and requires tremendous attention to detail, compliance, and support. Because of these challenges and the relative rarity and biologic heterogeneity of the disease, it is recommended that patients are referred to larger academic centers for the evaluation and treatment to ensure the best possible survival rates. In the ensuing sections, the various components of treatment are reviewed. Special attention to the treatment of certain disease subsets are addressed because treatment of ALL is becoming increasingly based on its heterogeneity and the ability to adapt therapy to each of these subsets.

Effective chemotherapy regimens must be supplemented with adequate supportive care measures to obtain the best patient outcomes. Given the highly immunosuppressive nature of ALL treatment regimens, prophylaxis for *Pneumocystis carinii* with trimethoprim–sulfamethoxazole should be initiated early during treatment and continue throughout the consolidation and maintenance phases of chemotherapy. It is also reasonable to consider antifungal and antiviral prophylaxis during periods of neutropenia. Consideration may be given to antibacterial prophylaxis during periods of neutropenia. Fluoroquinolones such as levofloxacin are the preferred agent, although the optimal antibiotic choice should depend on local bacterial resistance patterns. Neutropenic fever in this group of patients must be treated as a medical emergency with immediate institution of intravenous (IV) antibiotics after obtaining the necessary cultures.

In an attempt to decrease the duration of neutropenia and improve remission rates, several groups have studied the role of granulocyte colony-stimulating factor (G-CSF) or granulocyte macrophage colony-stimulating factor (GM-CSF) during induction therapy. In the CALGB 9111 trial, 198 adults with untreated ALL were randomized to receive G-CSF (beginning 4 days after the start of induction until neutrophil recovery) versus placebo. The median time to neutrophil recovery (≥1000/μL for 2 days) significantly shortened to 16 days in the G-CSF arm compared with 22 days in the placebo arm. The duration of hospitalization was also significantly shorter in the G-CSF arm. There was a trend toward increased CR rate in the G-CSF arm. However, the infectious complications, disease-free survival (DFS), and overall survival (OS) were similar in the two arms. Thomas and colleagues randomized 236 ALL patients treated on the LALA-94 trial to receive G-CSF, GM-CSF, or no CSF. Use of G-CSF was associated with a significant decrease in time to neutrophil recovery, duration of hospitalization, and infections that were grade 3 or higher. Thus, use of G-CSF can allow for faster hematopoietic recovery, especially in elderly patients, and may decrease infectious complications; however, the prophylactic use of G-CSF has not been uniformly adopted, and many studies simply follow standard guidelines for use of growth factors in the setting of neutropenic fever.

All patients should be monitored carefully for tumor lysis syndromes especially those with risk factors such as elevated WBC counts, renal dysfunction, and elevated LDH at presentation. Patients must be provided adequate hydration and prophylaxis or treatment for hyperuricemia with allopurinol for the first week of induction. Rasburicase, a urate oxidase, can be considered for the treatment of hyperuricemia in cases with high proliferation rates.

REMISSION INDUCTION

The aim of induction therapy is to achieve maximal reduction of the leukemic burden to result in morphologic remission (<5% blasts with trilineage hematopoiesis) and normalization of the blood counts, with as little toxicity as possible. This is typically achieved using combination chemotherapy consisting of four or five systemically administered drugs and intrathecal chemotherapy over a period of approximately 3 to 4 weeks. Most current ALL induction regimens in adults are modeled after pediatric regimens and include a prolonged course of oral corticosteroid (prednisone or dexamethasone), weekly vincristine, and either weekly or pulsed anthracycline (doxorubicin, daunorubicin, or mitoxantrone). Many groups (CALGB, French GRAALL 2003, and BFM) have also used twice-weekly L-asparaginase as part of induction therapy and some have added cyclophosphamide (MD Anderson, GRAALL 2003, and GMALL 07/2003). With the current treatment regimens, very high CR rates in adults with ALL have been achieved in the range of 84% to 94% (Table 65-6). There have been few randomized comparisons between these different induction regimens; therefore, the choice of the regimen should depend on the treating physician's experience with a particular regimen. Most ALL regimens are designed to optimally deliver a variety of chemotherapeutic agents; thus, an entire treatment program should be selected at the time of diagnosis based on the patient's performance status and biologic risk factors. Whenever possible, these patients should be referred to centers that offer expertise in the treatment of ALL and where enrollment into clinical trials is available.

Traditionally, prednisone was the corticosteroid of choice during induction therapy for ALL trials. Studies in pediatric patients have shown lower relapse rates but higher toxicity (more sepsis, higher incidence of osteonecrosis) with dexamethasone. Dexamethasone penetrates the blood–brain barrier effectively and therefore may offer more direct CNS protection than prednisone. Comparative studies of prednisone versus dexamethasone have not been performed in adults, and some groups have incorporated prednisone (CALGB 10403, GRAALL-2003, and BFM); others have incorporated dexamethasone (CALGB 10102, MD Anderson, GMALL 07/2003) during the induction cycle. Anthracyclines form an important part of induction therapy. In an early trial from the CALGB (7612), patients were randomized to receive vincristine, prednisone, and L-asparaginase with or without daunorubicin. Significant improvements in CR rates and remission duration were noted with the addition of daunorubicin; anthracyclines have since become standard components of induction chemotherapy in adult and pediatric ALL. Different anthracyclines (doxorubicin, daunorubicin, and mitoxantrone) are thought to be clinically equivalent and, to date, dose intensification of anthracycline during induction has been tested in a variety of prospective clinical trials but has not been shown to definitely improve already high CR rates or to result in significant benefits in DFS. Addition of pulsed cyclophosphamide to induction chemotherapy has been studied with conflicting results. In the CALGB 8811 trial, addition of cyclophosphamide to the induction regimen was shown to lead to improved responses compared with historical control participants. However, in a prospective, randomized Italian GIMEMA 0288 study, the addition of cyclophosphamide did not influence CR rate or survival.

One of the regimens that is widely used in the United States and also results in high CR rates of approximately 90% is the hyper-CVAD (cyclophosphamide, vincristine, Adriamycin, and dexamethasone) regimen developed at the MD Anderson Cancer Center. The hyper-CVAD regimen differs from the pulsed weekly therapy developed by the pediatric groups and consists of four cycles of intensive infusional cyclophosphamide, vincristine, doxorubicin, and dexamethasone alternating with four cycles of high-dose methotrexate and high-dose cytarabine for a total of eight intensive treatment cycles.

Table 65-6 Clinical Trials With Various Chemotherapy Regimens for Adult Acute Lymphoblastic Leukemia

Trial	Patients *(n)*	Age in Years, Median (Range)	CR Rate (%)	Disease-Free Survival	Overall Survival	Comments
CALGB 8811[1]	197	32 (16-80)	85	46% at 3 years	36 months (median)	Five-drug induction regimen based on pediatric trials with earlier and more intensive L-asparaginase
CALGB 9111[2]	198	35 (16-83)	85	40% at 3 years	23 months (median)	Patients randomized to G-CSF vs. placebo; G-CSF significantly decreased time to neutrophil recovery and CR rate with no effect on DFS, OS, or toxicities
MDACC hyper-CVAD[3]	288	40 (15-92)	92	38% at 5 years	32 months (median)	Long-term follow-up results of hyper-CVAD regimen; regimen does not include asparaginase
GMALL 05/93[4]	1163	35 (15-65)	83		35% at 5 years	
GMALL 07/2003[5]	713	34 (15-55)	89		54% at 5 years	Risk-adapted SCT for HR and very HR groups
LALA 94[6]	922	33 (18-79)	84	30% at 5 years	23 months (median)	CR rate similar between IDA and DNR arms; significantly higher TRM with IDA; improved DFS for the IDA arm for patients receiving only chemotherapy; for SR patients, intensive consolidation did not affect outcomes
JALSG ALL-93[7]	263	31 (15-59)	78	30% at 6 years	33% at 6 years	Doxorubicin dose intensity did not improve outcomes; during maintenance phase, early sequential intensification compared with intermittent intensification did not affect DFS
JALSG ALL-97[8]	404	38 (15-64)	74	33% at 5 years	32% at 5 years	Induction and maintenance based on CALGB 8811; dose intensive doxorubicin during consolidation did not improve outcomes
GIMEMA 0288[9]	778	28 (12-60)	82	33% at 9 years	29% at 9 years	Addition of cyclophosphamide to induction did not influence CR rate or survival; responders to prednisone pretreatment had favorable outcomes
MRC UKALLXII/ECOG E2993[10]	1646 (Ph-)	(15-64)	90		43% at 5 years	Largest ALL trial to date; in a donor vs. no-donor analysis, those with a donor had improved OS and lower relapse rate; ASCT cannot replace consolidation or maintenance chemotherapy in any risk group
PETHEMA ALL-93[11]	222 high-risk ALL	27 (15-50)	82	35% at 5 years	34% at 5 years	Did not show beneficial effect of aSCT compared with ASCT or chemotherapy
GRAALL-2003[12]	225 Ph- ALL	31 (15-60)	94	59% at 3.5 years	60% at 3.5 years	Pediatric-inspired treatment regimen; in a historical comparison, significant increases in CR, EFS, and OS rates compared with LALA-94 trial; OS was improved for patients younger than 45 years only

ALL, Acute lymphoblastic leukemia; *aSCT,* allogeneic stem cell transplantation; *ASCT,* autologous stem cell transplantation; CALGB, Cancer And Leukemia Group B; *CR,* complete remission; *CVAD,* cyclophosphamide, vincristine, Adriamycin, and dexamethasone; *DFS,* disease-free survival; *DNR,* daunorubicin; *G-CSF,* granulocyte colony-stimulating factor; *HR,* high risk; *IDA,* idarubicin; *OS,* overall survival; *SCT,* stem cell transplantation; *SR,* standard risk; *TRM,* transplant-related mortality.

Some groups have also instituted a 5- to 7-day steroid prophase before starting the induction therapy. This results in gentle cytoreduction and reduces the risk of tumor lysis. The achievement of rapid cytoreduction during this steroid prophase has also been shown to be of prognostic value in several studies.

In summary, although all of the currently employed induction regimens in adults with ALL now routinely result in these very high CR rates of 80% to 90%, none of them has yet translated into the 80% to 85% DFS rates that are routinely achieved in pediatric ALL. In adult ALL, DFS generally has been reported to be at 40% to 45% at 3 years and 30% to 35% at 5 years (see Table 65-6). Thus, the main problem with the current treatment programs in adult ALL is disease relapse from the emergence of resistant disease and not in the failure to achieve CR.

POSTREMISSION THERAPY

As mentioned earlier, 80% to 90% of adults with previously untreated ALL achieve CR with induction chemotherapy. However, all patients

relapse if no further chemotherapy is given. This underscores the need for effective postremission management strategies for these patients in first CR (CR1). As described earlier, adult patients with ALL have traditionally been stratified into SR or HR.

The type of postremission strategy is recommended to be based on the risk (risk-adapted approach), which implies more aggressive therapeutic approaches for HR groups compared with SR group. There have been three tested approaches for postremission therapies: (1) postremission chemotherapy modules followed by long-term maintenance chemotherapy; (2) allo-SCT; and least frequently, (3) autologous stem cell transplant (ASCT). Studies using these postremission strategies are reviewed below.

The optimal postremission strategy for SR adult patients is not clear. Conventionally, consolidation and maintenance chemotherapy has been the recommendation for this group of patients, given lower potential for toxicities and up to 40% to 60% survival at 5 years with this approach. Postremission chemotherapy typically consists of a variety of non–cross-resistant chemotherapeutic agents administered in treatment "modules" for a total of 6 to 8 months after achievement of remission. The postremission modules are typically 4 to 6 weeks in length and are modeled after successful pediatric regimens and often consist of consolidation module(s), interim maintenance modules that often focus on CNS prophylaxis (described in more detail below); and late intensification module(s), which is often quite similar to the induction chemotherapy course. The specific drugs and the sequence or combinations in which they used are different for each protocol but typically include cyclophosphamide, L-asparaginase (or pegasparaginase), methotrexate, cytarabine, 6-mercaptopurine, vincristine, and doxorubicin. Many of these protocols have evolved empirically with few randomized trials evaluating the impact of any of the modifications that have been developed (see Table 65-6).

A different approach to postremission therapy has been taken by the MD Anderson Cancer Center, which have reported long-term results of the hyper-CVAD regimen (also listed in Table 65-6). As described earlier in the induction section, patients received alternating cycles of hyperfractionated cyclophosphamide, vincristine, adriamycin, and dexamethasone hyper-CVAD (courses 1, 3, 5, and 7) alternating with high-dose methotrexate and cytarabine (courses 2, 4, 6, and 8) followed by maintenance therapy for 2 years with 6-mercaptopurine, methotrexate, vincristine, and prednisone (POMP). They identified the following factors to be independent poor prognostic factors for survival: older age, Ph^+ disease, leukocytosis, thrombocytopenia, poor performance status, and hepatomegaly. The 5-year OS for the good-risk (risk score, 0-1), intermediate risk (risk score, 2-3), and poor-risk groups (risk score, ≥4) were 62%, 34%, and 5%, respectively.

In summary, despite attempts to intensify postremission therapy with high doses of cytarabine and anthracycline, the OS rate of patients in all of the studies published in the past decade is approximately 30% to 50%, depending on risk factors and treatment approach. Notably, adults older than the age of 60 years have uniformly fared poorly with OS below 10%. Table 65-6 summarizes the major treatment questions, therapeutic approach and results of several of the recent large prospective cooperative group trials in the United States and Europe.

CENTRAL NERVOUS SYSTEM DISEASE: PROPHYLAXIS AND TREATMENT

Involvement of the CNS (Fig. 65-6) is uncommon at the time of diagnosis with most series reporting it at less than 10%. However, because many patients with CNS involvement may not be referred for clinical trial enrollment, this may be an underestimate of the true rate. In the MRC UKALL XII/ECOG E2993 trial, of the 1508 eligible patients, 77 (5%) had CNS involvement at diagnosis. Similarly, the French group reported a 7% (104 of 1493 patients) incidence of CNS disease at diagnosis. Risk factors for CNS disease at diagnosis have been varied in different studies. In the French trial (LALA-87 and LALA-94), risk factors included mediastinal mass associated with precursor T-cell immunophenotype, lymphadenopathy, higher hemoglobin level, and absence of the Philadelphia chromosome. In the MRC trial, the risk factors included a higher WBC count, precursor T-cell immunophenotype, and mediastinal mass. The presence of CNS disease at diagnosis has been shown not to affect the CR rate. The French group also reported no significant difference in the OS in patients with and without CNS disease at diagnosis. However, in the MRC trial, the OS at 5-year was lower in the CNS disease group (29% vs. 38%; $P = .03$), and they also reported that patients with CNS disease at diagnosis were twice more likely to relapse in the CNS. In the French study, younger age (<30 years), male gender, absence of the Ph chromosome, achievement of CR with one course, and use of transplant as postremission therapy had favorable impact on OS for patients presenting with CNS disease at diagnosis.

Induction therapy of ALL usually includes a lumbar puncture with introduction of intrathecal chemotherapy. For those presenting with CNS disease at diagnosis or in whom CNS disease develops later in the course of the treatment, immediate intensified CNS treatment is imperative. These patients should receive intrathecal chemotherapy (intrathecal methotrexate alone or together with cytarabine and steroid [triple intrathecal therapy]) twice-thrice weekly until clearing of cerebrospinal fluid along with initiation of systemic chemotherapy. Cranial irradiation (2400 cGy over 12 fractions) is considered necessary for the successful treatment of CNS disease with cranial nerve involvement.

Central nervous system prophylaxis is an essential component of therapy for all patients given the high incidence (30%-40%) of CNS relapse if the CNS prophylaxis is omitted. Now with the universal

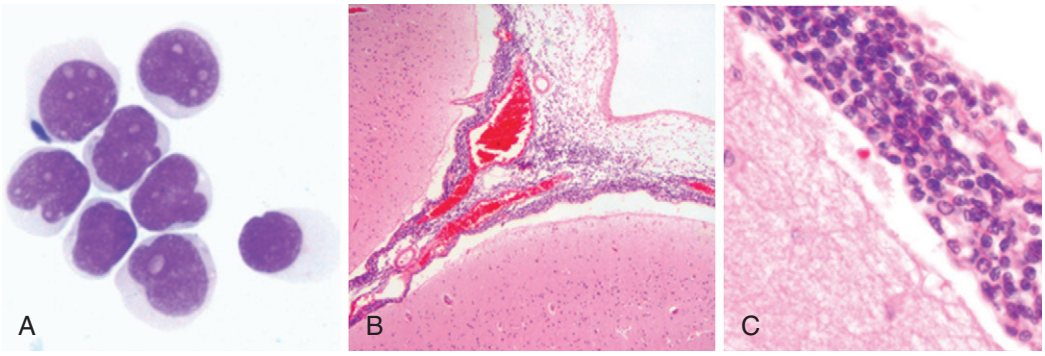

Figure 65-6 CEREBROSPINAL FLUID (CSF), AND CENTRAL NERVOUS SYSTEM DISEASE. Blasts in the CSF can be identified on a cytospin preparation. They have similar cytologic features as the blasts in the blood or bone marrow aspirate **(A).** Histologic section of the brain is illustrated from a patient with ALL and leukemic meningitis. The sections show blasts within the leptomeninges (**B;** higher power, **C**).

adoption of CNS prophylaxis in the treatment regimens, the rates of CNS relapse have decreased substantially. CNS prophylaxis is typically administered by multiple rounds of intrathecal chemotherapy that are staggered over the entire treatment duration. In addition, the use of high-dose methotrexate and cytarabine also provides for CNS prophylaxis because both agents penetrate the blood–brain barrier. The intensive use of high-dose systemic methotrexate and frequent intrathecal therapy has often replaced the more traditional combination of CNS irradiation and intrathecal therapy that were the hallmarks of the earlier ALL regimens. This non–radiation-containing approach has resulted in effective CNS protection with rates of CNS relapse now routinely reported as occurring in fewer than 5% to 10% of cases. Adolescents and young adults (AYAs) treated on pediatric regimens with more intensive CNS prophylaxis have reported CNS relapse rates as low as 1%. The omission of cranial irradiation may prevent neurocognitive damage in adults. Although this has not been demonstrated in adult studies, definitive evidence from pediatric studies indicates that avoidance of cranial irradiation may prevent declines in cognitive function.

MAINTENANCE THERAPY

The goal of maintenance treatment is to prevent disease relapse by elimination of leukemia clones by long-term exposure to cytotoxic drugs. One of the commonly used regimens uses daily 6-mercaptopurine and weekly oral methotrexate with monthly vincristine and prednisone (POMP regimen). Some groups replaced prednisone with dexamethasone. The duration of maintenance treatment is generally 2 to 3 years (2 years for women and 3 years for men). Similar to the other components of adult ALL regimens, the adoption of long-term maintenance therapy derives from the benefit of maintenance therapy that has demonstrated in pediatric trials.

Although the benefit of maintenance therapy in adult trials has not been demonstrated in randomized trials, it has been shown that omission of maintenance treatment leads to worse clinical outcomes. In a CALGB study, 164 newly diagnosed ALL patients were randomized to receive daunorubicin or mitoxantrone during induction followed by 4 cycles of consolidation. No maintenance therapy was planned. There were significantly more relapses noted in this study with median remission duration of only 10 to 12 months. The study was stopped earlier than planned because remission duration was shorter than in historical control participants who had received maintenance therapy. Similar results were obtained by the Dutch-Belgian Haemato-Oncology Cooperative Group (HOVON), which treated 130 ALL patients with induction followed by 3 cycles of consolidation. No maintenance therapy was given. The estimated 5-year OS and DFS were only 22% and 28%, respectively. Pediatric regimens routinely incorporate CNS prophylaxis during the maintenance phase. Pediatric studies have also reported favorable impact on DFS of achieving adequate myelosuppression with the chemotherapy drugs during the maintenance phase. Thus, it appears that careful adjustment of the doses of the oral agents used during maintenance therapy to achieve optimal yet safe myelosuppression improves treatment outcomes.

ALLOGENEIC STEM CELL TRANSPLANT IN FIRST COMPLETE REMISSION

Despite attempts to improve DFS in adult ALL, OS with the standard chemotherapy regimens described above has been "fixed" at about 35% to 45% for the past decade. Thus, several groups have evaluated the role of treatment intensification with transplant (both aSCT and ASCT) as postremission therapy and compared the outcomes with the traditional chemotherapy approaches described previously. Conventionally, an aSCT has been reserved as the standard recommendation for only HR patients in CR1. In one of the earliest randomized trials to investigate the role of allogeneic transplant, the French LALA-87 study, patients in CR1 were assigned to donor group (if they had an HLA-matched related donor); the remaining patients (no-donor group) were randomized to ASCT versus chemotherapy. In this study, patients with HR ALL (defined as the presence of Philadelphia chromosome, or null leukemia [defined by a CD10- , CD20-immunophenotype], undifferentiated leukemia, or common leukemia with at least one adverse prognosis factor such as age older than 35 years, WBC count greater than 30,000/μL, or time to CR longer than 4 weeks) benefitted from aSCT. For the HR group, 5-year OS was 44% in the donor arm (n = 41), which was significantly better than the 20% in the no-donor arm (n = 55) (P = .03). The outcome of SR group was not improved with aSCT (5-year OS of 51% in the donor arm vs. 45% in the no-donor arm). Similar results were seen in a follow-up of LALA-94 trials with benefit of aSCT in HR group. In contrast, the Program Español de Tratamiento en Hematologia (PETHEMA) ALL-93 trial failed to show benefit of aSCT in HR ALL patients.

In a recently published trial, the MRC UKALLXII/ECOG E2993 trial, all patients (younger than 50 years or 55 years or younger after 2003) in CR1, irrespective of risk status, were assigned to aSCT if they had an HLA-compatible sibling donor. All other patients were randomized to consolidation or maintenance therapy or to an ASCT. In this largest adult ALL trial to date, 1646 Ph-negative patients were enrolled; 1484 (90%) achieved CR1. After excluding patients who were older than 55 years old and those without available HLA typed siblings, 1031 CR1 patients (55% SR; 45% HR) were HLA typed. In a "genetic randomization" approach using donor (n = 443) versus no-donor (n = 588) analysis, OS benefit was seen for the donor arm when all patients were considered (5-year OS, 53% vs. 45%; P = .01). In a subgroup analysis, the survival benefit of transplant was restricted to patients who were younger than 35 years old. For patients older than 35 years of age or with adverse cytogenetics, OS was not better than with standard chemotherapy because of transplant-related toxicities, which resulted in early deaths.

In a report by the Dutch-Belgian HOVON group, patients younger than 50 to 55 years in CR1 were offered an aSCT. In a donor (n = 96) versus no-donor (n = 161) analysis for all patients, 5-year OS was 61% for the donor arm compared with 47% in the no-donor arm (P = .08). In subset analysis, the survival benefit of transplant was restricted to SR patients, which were those without any of the following HR features: presence of a high WBC count at diagnosis (>30,000/μL in B-ALL or >100,000/μL in T-ALL), cytogenetic abnormalities [t(4;11), t(1;19), t(9;22)], pro–B-cell immunophenotype, and CR achievement longer than 4 weeks from start of induction.

A meta-analysis of seven studies (with 1274 patients) that prospectively assessed OS using genetic randomization based on donor availability reported significantly better OS in the donor group versus the no-donor groups (hazard ratio; 1.29; P = .037), which was more pronounced in patients with HR features.

Alternative Stem Cell Sources; Alternative Preparative Regimens for Allogeneic Stem Cell Transplantation

Matched-sibling donors (MSDs) remain the preferred modality for the stem cell source (Table 65-7). For patients lacking an MSD, a matched unrelated donor (MUD) or an alternative donor source (e.g., umbilical cord blood [UCB]) should be pursued. In a Center for International Blood and Marrow Transplant Research (CIBMTR) registry study, outcomes of 169 patients with ALL in CR1 who underwent unrelated donor transplants between 1995 and 2004 were analyzed. A total of 41% were HLA well matched, 41% partially HLA matched, and 18% HLA mismatched. The majority (93%) of the patients had at least one HR feature. One-year transplant-related mortality (TRM) was high at 36%, and TRM at 5 years was 42%. The relapse rate at 5 years was 20% with 5-year DFS and OS of 38% and 39%, respectively. Factors associated with worse survival included

Table 65-7 Clinical Trials Evaluating Role of Myeloablative Allogeneic Stem Cell Transplant in Acute Lymphoblastic Leukemia

Trial	Patients *(n)*	Age in Years, Median (Range)	Conditioning Regimen/Donor	TRM	DFS/OS	Comments
GOELAL02[1]	41 (HR)	34 (15-52)	Etoposide/cyclophosphamide/TBI (12 Gy in 6 fractions) MSD	15%	DFS: 75% at 6 years; OS: 75% at 6 years	Showed improved survival with aSCT compared with ASCT
LALA 94[2]	100 (HR ALL excluding Ph^+ ALL)	33 (15-55) for the entire study cohort of 922 patients	Cyclophosphamide/TBI (10 Gy as a single dose or 12 Gy in 6 fractions) MRD	18% at 3 years	3-year DFS: 47%	For high-risk ALL, aSCT was superior to an ASCT
PETHEMA-93[3]	222 HR patient underwent MSD (if available); if not, randomized to ASCT vs. chemotherapy	27 (15-50)	Cyclophosphamide/TBI (12 Gy in 6 fractions) MSD		5-year OS: 35%	No benefit of an MSD transplant for HR patients (compared with ASCT or chemotherapy only approach)
MRC UKALLXII/ ECOG E2993[4]	Patients assigned to aSCT if an MSD available (donor group); those without donors randomized to ASCT vs. chemotherapy	15-64	Etoposide/TBI (13.2 Gy in 6 fractions) MSD	NRM High risk (36% donor; 14% no-donor); Standard risk (20% donor; 7% no donor)	5-year OS: HR (41% donor, 35% no donor) SR (62% donor vs. 52% donor)	Beneficial effect of all-SCT limited to SR group only; relapse rate decreased with aSCT in both HR and SR groups
HOVON[5]	ALL in CR1 according to sibling donor vs. no-donor comparison HR: 46 donor; 73 no donor SR: 50 donor; 88 no donor	Donor 31 (16-55)	Cyclophosphamide/TBI (12 Gy in 6 fractions) MRD	HR: NRM at 5 years (15% donor vs. 4% no-donor) SR: NRN at 5 years (16% donor vs. 2% no-donor, $P = 0.01$)	HR: OS at 5 years (53% donor vs. 41% no donor) SR: OS at 5 years (69% donor vs. 49% no donor, $P = .05$)	Similar to the MRC UKALLXII/ ECOG E2993 trial, benefit of aSCT seems limited to SR patients

ALL, Acute lymphoblastic leukemia; *aSCT,* allogeneic stem cell transplantation; *ASCT,* autologous stem cell transplantation; *CR1,* first complete remission; *DFS,* disease-free survival; *HR,* high risk; *MRD,* minimal residual disease; *MSD,* matched-sibling donor; *OS,* overall survival; *SCT,* stem cell transplantation; *SR,* standard risk; *TBI,* total-body irradiation; *TRM,* transplant-related mortality.

WBC greater than 100×10^9/L, time to CR1 longer than 8 weeks, cytomegalovirus seropositivity, HLA mismatching, and T-cell depletion. The Minnesota group recently reported outcomes of myeloablative aSCT for ALL patients transplanted at their center and compared retrospectively the outcomes with respect to different donor sources. In an analysis restricted to 91 adult patients who received aSCT in CR1or CR2 from 1990 to 2005, there was no difference between the allogeneic donor sources (matched related donor vs. matched URD vs. UCB donor) for OS, DFS, or TRM.

Because the majority of older adults are not candidates for a myeloablative aSCT, reduced-intensity conditioning (RIC) approaches have been explored in this patient population (Table 65-8). The Seattle group recently reported outcomes of aSCT using nonmyeloablative conditioning in 51 patients with ALL (median age, 56 years), half of whom were Ph positive. For the Ph-negative group, the 3-year OS for those transplanted in CR1 was 52%. The incidence of chronic graft-versus-host disease, however, was high at 44%. A recent registry study examined the efficacy of RIC in 93 ALL patients and compared it with 1428 ALL patients receiving myeloablative conditioning for aSCT using either a sibling or unrelated donor in CR1/CR2. Interestingly, the TRM at 3 years was similar between the RIC and myeloablative regimens (32% vs. 33%, respectively). The relapse rate at 3 years was slightly higher in the RIC arm, although this was not statistically significant (35% vs. 26%; $P = .08$). The OS at 3 years was similar between the two groups (38% for RIC arm vs. 43% for myeloablative arm, $P = .39$). This was a retrospective registry study; however, it provides evidence that RIC regimens can lead to similar survival in adults with ALL as aSCT with a more intensive, myeloablative conditioning regimen. This is particularly compelling because the median age was significantly older for those receiving RIC (median age in RIC arm, 45 years vs. 28 years for myeloablative arm). The group from Minnesota has also reported encouraging results with the of UCB donor transplantation using a RIC regimen. Eighteen adults (median age, 49 years; range, 24-68 years) with high-risk ALL (majority Ph^+ ALL) received a with a cord blood transplant using a RIC conditioning regimen and reported 3-year OS, TRM, and relapse rates of 49%, 28%, and 33%, respectively. Notably, patients in CR1 had a TRM of only 8% with no events after 6 months. These results with UCB donor transplantation are promising and compare favorably to conventional aSCT with relatively low TRM in this high-risk population. Thus, RIC-based aSCT regimens with alternative donor sources should be considered for older adults in prospective clinical trials.

In summary, aSCT is a curative option for patients with ALL and can be considered the standard recommendation for patients with a good performance status but with adverse disease risk factors in CR1. There have been significant improvements in transplantation techniques (better supportive care, refinement of preparative regimens, uses of alternative donors as a source of stem cells) that are resulting in greater availability and improved transplant outcomes. At the same time, the TRM and mortality are significant, and aSCT has largely been offered only to patients younger than 60 years of age because of the poor tolerance of older adults to standard myeloablative transplant preparative regimens. Prospective incorporation of MRD evaluation may refine the ability to risk stratify patients who are at high risk of relapse and might benefit from aSCT in CR1. However, the benefit of a SCT for MRD-positive patients remains to be proven and has only been studied prospectively in a single study to date. Conversely, patients who were MRD negative in CR1 may best be treated by chemotherapy alone. Overall, the role of aSCT in CR1 merits further study, and it is important to refer these patients to clinical trials exploring such approaches.

Table 65-8 Clinical Trials Evaluating Role of Reduced-Intensity Conditioning Allogeneic Stem Cell Transplant in Acute Lymphoblastic Leukemia

Trial	Number of Patients	Age in Years, Median (Range)	Conditioning Regimen/Donor	Mortality	DFS/OS	Comments
Arnold[1]	22 (11 Ph^+)	38 (21-58)	Fludarabine/busulfan +/– ATG MSD or MUD	TRM: 45%	Median survival: 354 days	High TRM of the group; all patients with aGVHD had CR indicating toward GVL effect
Martino[2]	27 (11 Ph^+)	50 (18-63)	Fludarabine/melphalan (most cases) MSD or MUD	2-year TRM: 23%	2-year OS: 31%	100-day acute grade II-IV GVHD: 48%; cGVHD 72% (extensive in 39%)
Hamaki[3]	33 (14 Ph^+)	55 (17-68)	Different RIC regimens MSD or MUD	TRM: 27%	1-year OS: 39.6%	Grade II-IV aGVHD: 45%; cGVHD: 64%

Autologous Stem Cell Transplantation

ASCT in CR1 has also been studied prospectively in several clinical trials. Dhedin and colleagues reviewed the data from the French LALA 85, 87, and 94 trials and compared the outcomes of patients in CR1 who were randomized to chemotherapy versus ASCT. There was no improvement in DFS or OS with the use of ASCT compared with postremission chemotherapy, but there was a lower incidence of relapse at 10 years (66% vs. 78%; $P = .05$). In the MRC UKALLXII/ECOG E2993 trial, 456 patients were randomized to chemotherapy versus ASCT in CR1. Patients randomized to chemotherapy had significantly better 5-year EFS (41% vs. 32%; $P = .02$); and OS (46% vs. 37%; $P = .03$). Thus, outside of a clinical trial, an ASCT cannot be recommended for ALL patients.

THERAPY FOR SPECIFIC DISEASE SUBSETS

Philadelphia Chromosome Positive Acute Lymphoblastic Leukemia

The Philadelphia chromosome [t(9;22)(q34;q11)], is the most common cytogenetic abnormality in adult ALL, and its incidence increases with age. Among patients older than 60 years old, 40% to 50% have the Philadelphia chromosome. Before the introduction of molecularly targeted therapy, Ph$^+$ ALL was associated with lower remission rates and a very poor prognosis with a median survival time of only approximately 9 months.

With the introduction of therapy using ABL-TKIs targeted to the aberrant BCR-ABL protein, the outcome of Ph$^+$ ALL has improved substantially and has been the major treatment advance for adults with ALL in the past 2 decades. Imatinib, the first targeted TKI developed for use in Ph$^+$ leukemias, has been combined with combination chemotherapy by various groups and this has substantially improved both CR rates and DFS (Table 65-9).

The MD Anderson was the first to report on the combination of imatinib with chemotherapy (hyper-CVAD). They used imatinib 600 mg/day on days 1 to 14 of induction, 600 mg continuously during courses 2 to 8 chemotherapy cycles, 800 mg during 2 years of maintenance therapy with monthly vincristine and prednisone, and then imatinib indefinitely. Thomas and colleagues recently reported long-term results of the Hyper-CVAD–Imatinib trial. The 3-year CR duration and OS rates were significantly superior in the hyper-CVAD–imatinib arm compared with historical control participants treated with hyper-CVAD alone (68% vs. 24% and 54% vs. 15%, respectively; $P < .001$). The Japanese have also reported impressive improvements compared to their control participants. In the JALSG ALL202 trial, imatinib, 600 mg/day, was added to standard induction followed by alternating cycles of high-dose methotrexate and high-dose cytarabine and imatinib 600 mg/day. Later maintenance therapy with imatinib 600 mg/day with monthly vincristine and prednisone was given. In a recent update, they reported results on 103 patients with Ph$^+$ ALL with a 97% CR rate and 3-year OS of 57%, both of which were significantly better than in historical control participants.

Older adults with Ph$^+$ ALL have also demonstrated improved survival with the addition of imatinib to chemotherapy regimens. Ottmann and colleagues reported for the German study group in which elderly (older than 55 years old) Ph$^+$ ALL patients were randomized to receive induction cycle with imatinib alone ($n = 28$) versus combination chemotherapy ($n = 27$). The CR rate was 96% in the imatinib arm, which was significantly better than the CR rate of 50% in the chemotherapy alone arm. This is the first prospective randomized controlled trial comparing imatinib with chemotherapy and clearly showed the superiority of the imatinib arm. There was no difference in the two arms with respect to DFS and OS, likely from the fact that all patients received imatinib-based consolidation or maintenance therapy. The Italian GIMEMA group treated 30 Ph$^+$ ALL patients (median age, 69 years; range, 61-83 years) with 7-day steroid pretreatment followed by induction treatment with only imatinib (800 mg/day) plus steroids. Impressively, all 29 evaluable patients achieved CR with 1-year DFS and OS of 48% and 74%.

There is general consensus that early TKI therapy is crucial, and most current treatment protocols include chemotherapy with continuous TKI therapy. In general, the TKI has been started with induction chemotherapy and continues throughout postremission therapy. However, Bassan and colleagues reported on 59 patients with Ph$^+$ ALL (NILG 09/00) in whom imatinib (600 mg/day) was added to each chemotherapy course for only 7 days, starting 3 days before chemotherapy, based on the hypothesis that imatinib would sensitize Ph$^+$ ALL cells to standard chemotherapy drugs. They reported a 92% CR rate with a 5-year OS of 38%.

Despite these significant advances in the treatment of Ph$^+$ ALL, relapses are still major challenges. Resistance to imatinib develops and most frequently results from the emergence of a resistant clone with ABL kinase domain mutations. These kinase domain mutations, including the frequently occurring T315I mutation, cause conformational changes in the ABL protein that prevent effective imatinib binding. Other potential mechanisms of resistance that have been described include reduced intracellular availability of imatinib and activation of alternative signaling pathways such as the Src-kinase pathways. Second-generation TKIs, dasatinib and nilotinib, are more potent kinase inhibitors and are also effective against many imatinib-resistant mutations (although not the T315I mutation). In addition, dasatinib has been shown to penetrate the CNS and thus may be particularly effective for ALL therapy.

Dasatinib has now been tested in several prospective trials for previously untreated Ph$^+$ ALL. MD Anderson investigators evaluated hyper-CVAD plus dasatinib in newly diagnosed Ph$^+$ ALL patients. Dasatinib, 100 mg/day, was given for the first 14 days of each of 8 cycles of alternating hyper-CVAD and high-dose cytarabine and methotrexate. Maintenance chemotherapy consisted of daily dasatinib 100 mg/day with monthly vincristine and prednisone for 2 years followed by dasatinib indefinitely. The median age of the 35 patients studied was 53 years (range, 21-79 years); 94% achieved CR. Of the patients who achieved CR, 61% patients achieved complete molecular remission, meaning that there was no detectable MRD using quantitative PCR for *BCR-ABL*. In a recent update to the hyper-CVAD and dasatinib study, the MD Anderson group reported that 24% patients underwent aSCT (16% in CR1; 8% CR2), and 3-year DFS and OS for the entire cohort were 49% and 62%, respectively. Foa and colleagues recently reported the results of the GIMEMA LAL1205 study in which dasatinib monotherapy (70 mg twice daily) with steroids was investigated for frontline treatment of 53 adult Ph$^+$ ALL patients (median age, 54 years). All patients achieved a complete hematologic response (CHR), and there were no induction deaths. BCR-ABL transcript levels decreased rapidly during induction therapy, and the percentage of patients achieving BCR-ABL levels below 0.001% increased from 23% at day 22 to 52% at day 85. Allo-SCT in CR1 was done in 18 (34%) patients. At 20 months, the OS was 69% and DFS was 51%. BCR-ABL levels of less than 0.001% at day 85 correlated with DFS. These results with dasatinib without any cytotoxic chemotherapy are encouraging but demonstrated that single-agent dasatinib is not sufficient to cure this disease.

Nilotinib is also a second-generation TKI that that has been evaluated in frontline therapy in a recently reported single-arm phase 2 study. Induction treatment consisted of vincristine, daunorubicin, oral prednisolone, and nilotinib (400 mg orallytwice daily). Patients in CR received either five courses of consolidation followed by 2-year maintenance therapy or an aSCT, depending on donor availability. Nilotinib was administered from day 8 of induction continuously until the end of maintenance or aSCT. Fifty consecutive patients were enrolled; 5 patients died during induction, and the remaining 45 (90%) patients achieved hematologic remission. More than 70% patients were able to receive aSCT. Estimated DFS and OS at 2 years were 71% and 66%, respectively, similar to rates observed with other

Table 65-9 Clinical Trials With Tyrosine Kinase Inhibitor Plus Chemotherapy for Adult Philadelphia Chromosome–Positive Acute Lymphoblastic Leukemia

Trial	Patients *(n)*	Age in Years, Median (Range)	CR Rate	Disease-Free Survival	Overall Survival	Comments
MDACC Hyper-CVAD Imatinib[1,2]	54	51 (17-84)	93%	68% at 3 years	In de novo patients 40 years of age or younger: 3-year OS was 90% with aSCT (n = 10) vs. 33% without aSCT (n = 6), P = .05.	First report of the combination of chemotherapy with a TKI Imatinib 600 mg/day on days 1-14 of induction; 600 mg continuously during courses 2-8; 800 mg during 2 years of maintenance therapy with monthly vincristine–prednisone; then imatinib indefinitely; allo-SCT in CR1 as feasible
JALSG ALL202[3-5]	103	45 (15-64)	97%	For those younger than age 55 years, 54 of 74 patients in CR1 who had aSCT, only 13% relapsed; among the 20/74 patients in CR1 who did not undergo SCT, 90% relapsed	57% at 3 years For patients younger than age 55 years, OS at 3 years was 75.0% for the transplanted group vs. 36.4% for the nontransplanted group	Standard induction plus imatinib 600 mg/day followed by alternating cycles of high-dose methotrexate and high-dose cytarabine and imatinib 600 mg/day; imatinib 600 mg/day with monthly vincristine–prednisone for maintenance
GRAAPH-2003[6,7]	45	45(16-59)	96%	43% at 4 years	52% at 4 years The 4-year OS in the aSCT, ASCT, and no SCT groups were 55%, 80%, and 25%, respectively	Imatinib was started with consolidation in good early responders (corticosensitive and chemosensitive ALL) or during the induction course in poor early responders
GMALL[8]	47 (alternating imatinib and chemotherapy)	46 (21-65)	NA because only CR patients were eligible	52% at 2 years	36% at 2 years	Coadministration of imatinib with induction cycle 2 led to CR rate of 95% and molecular CR rate of 52% of patients compared with 19% (significantly worse) in patients in the alternating treatment cohort
	45 (concurrent imatinib and chemotherapy starting after induction I)	41 (19-63)	95%	61% at 2 years	43% at 2 years	
GMALL[9]	28 (imatinib arm) 27 (chemotherapy arm)	66 (54-79) 68 (58-78)	96% 50% (significantly inferior to imatinib arm)	30% at 1.5 years 35% at 1.5 years	57% at 1.5 years 41% at 1.5 years	Patients older than age 55 years with de novo ALL and not eligible for aSCT; randomized to single-agent imatinib induction vs. multi-agent chemotherapy induction; subsequent
GIMEMA[10]	29	69 (61-83)	100%	48% at 1 year	74% at 1 year	7-day steroid pretreatment followed by induction treatment with imatinib (800 mg/day) plus steroids
NILG protocol 09/00[11]	59	45 (20-66)	92%	39% at 5 years	38% at 5 years	Imatinib (600 mg/day) was added to each chemotherapy course for 7 days starting 3 days before chemotherapy
UKALLXII/ ECOG2993[12]	175	Not reported	92%	54% at 3 years	42% at 3 years	Outcomes (CR, DFS, and OS) were significantly better compared with the historical pre-imatinib cohort; for the imatinib group, 3-year OS for patients who received aSCT was 59% vs. 28% for those who did not receive aSCT

ALL, Acute lymphoblastic leukemia; *aSCT,* allogenic stem cell transplantation; *ASCT,* autologous stem cell transplantation; *CR,* complete remission; *CR1,* first complete remission; *DFS,* disease-free survival; *NA,* not applicable; *OS,* overall survival; *SCT,* stem cell transplantation.

TKIs. Although these results are similar to other studies with dasatinib, most of the current trials in Ph+ ALL have incorporated dasatinib in the frontline therapy because of its potential advantage over nilotinib with respect to CNS penetration.

Role of Allogeneic Stem Cell Transplantation for Ph+ Acute Lymphoblastic Leukemia in the Era of Tyrosine Kinase Inhibitor–Based Therapy

Allo-SCT in CR1 has been the standard recommendation for Ph+ ALL in the pre-TKI era. Although the addition of TKI therapy has significantly improved the outcome of Ph+ ALL, many recent studies have also highlighted the continued role of aSCT for Ph+ ALL. In an update of the hyper-CVAD-imatinib protocol, the MD Anderson group reported that in a subgroup of patients younger than 40 years old, the 3-year OS was 90% with an aSCT compared with 33% without aSCT ($P = .05$). In the Japanese study, aSCT was performed in the CR1 in 54 of the 74 CR1 patients younger than 55 years of age. Relapse occurred in 13% (7 of 54) of the transplanted patients compared with 90% (18 of 20) in those who were not transplanted. Similarly, OS at 3 years was 75% for the transplanted group versus 36% for the nontransplanted group.

Similar results have been reported in preliminary form, by the MRC UKALLXII/ECOG E2993 trial group. In this study, 175 Ph+ ALL patients received imatinib plus chemotherapy (2003 onward). The authors reported that 44% of the patients were able to receive an aSCT per protocol, a number much higher than the 28% who were able to receive aSCT in the pre-imatinib era of this study (1993-2003). For the imatinib cohort, the 3-year OS for patients who received per protocol aSCT was 59% versus 28% for those who did not receive aSCT. In a recent update of the GMALL study, 219 of 335 (66%) Ph+ ALL patients treated with an imatinib-based chemotherapy regimen underwent aSCT in CR1. For the transplanted patients, the median OS was 57% after 3 years and 52% after 7 years compared with the dismal outcome of the nontransplanted group (3-year OS of only 14%). These studies provide a strong rationale for the continued recommendation for an aSCT in CR1 for Ph+ ALL patients.

The role and duration of TKI therapy after transplant is currently an area of active investigation. Wassmann and colleagues treated 27 Ph+ ALL patients with imatinib upon detection of MRD after SCT. Approximately 50% of patients achieved a molecular remission after a median of 1.5 months and these patients had a significantly longer time to progression (28.6 months vs. 3.6 months; $P < .001$) and OS (2-year OS, 80% vs. 23%; $P < .001$) compared with those who had persistent *BCR-ABL* transcript levels. The German group also reported results of a randomized study comparing prophylactic ($n = 26$) versus preemptive (after detection of bcr-abl transcripts, $n = 29$) imatinib after aSCT for Ph+ ALL. Imatinib was discontinued early in more than half the patients in both groups, mostly because of gastrointestinal toxicity. Prophylactic administration of imatinib significantly reduced the incidence of molecular relapse after the aSCT. The OS was similar in the two arms (5-year OS, 75%-80%). At the present time, it appears that continuing TKI therapy after transplant is an appropriate strategy. Studies evaluating MRD may provide guidance with the question of duration of posttransplant TKI therapy.

Newer TKIs such as ponatinib have shown promising activity in TKI-resistant Ph+ ALL and are discussed in the section Novel Therapies.

BURKITT LYMPHOMA/LEUKEMIA

Burkitt lymphoma is a mature B-cell lymphoma with an extremely short doubling time that often presents in extranodal sites or as acute leukemia. Thus, a brief description of the therapy is warranted in this chapter. Morphologically (Fig. 65-7), the malignant cells are intermediate in size, have round nuclei with small nucleoli, are intensely basophilic, and frequently have vacuolated cytoplasms. In BM biopsy and in tissue section, the tumor is classically described as having a "starry sky" appearance because of the presence of multiple tingible body macrophages with phagocytized cellular debris. Immunophenotypically, the tumor cells express moderate to strong levels of surface IgM with light chain restriction, indicating origin of the tumor from a mature B cell. The tumor cells also universally express the B-cell antigens CD19 and CD20 and germinal center associated markers such as CD10 and BCL6. Unlike B-ALL, BL cells do not express CD34 or TdT. The genetic basis of the disease is the underlying MYC translocation at band 8q24 to either the immunoglobulin heavy chain region on chromosome 14 or less commonly at the lambda (22q11) or kappa (2p12) loci.

Prompt diagnosis and recognition of this entity is essential because this is now highly curable leukemia (in the range of 65%-80% in recent trials); however, failure to institute appropriate therapy at diagnosis for Burkitt leukemia/lymphoma results in emergence of early resistance and dismal outcomes. Traditional CHOP (cyclophosphamide, hydroxydaunomycin, vincristine [Oncovin], and prednisone) chemotherapy is inadequate and should not be used. Treatment should be initiated quickly and consists of aggressive combination chemotherapy with CNS prophylaxis. These patients are at high risk for the development of tumor lysis syndrome; therefore, aggressive hydration and administration of allopurinol and/or rasburicase is important. All current regimens rely on short intensive courses of chemotherapy that incorporates fractionated doses of alkylating agents, high doses of methotrexate and cytarabine, and intensive

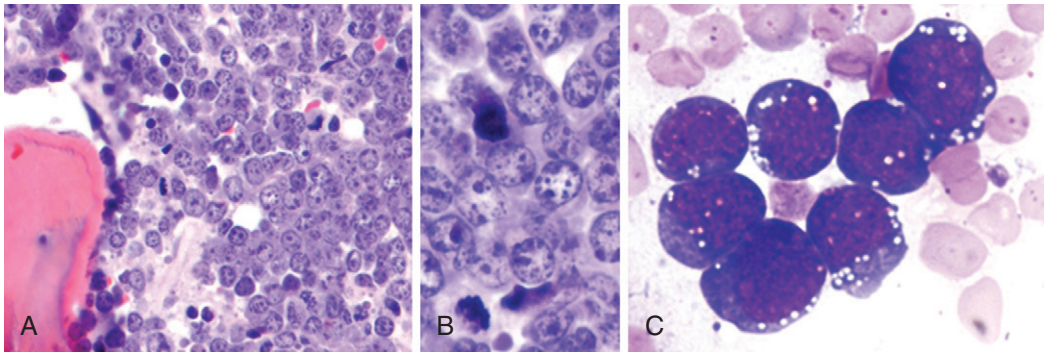

Figure 65-7 BURKITT LEUKEMIA/LYMPHOMA (**A** to **C**). Bone marrow biopsy and aspirate features of Burkitt leukemia/lymphoma are illustrated. The bone marrow (or lymph node) will show sheets of highly proliferating intermediate-sized neoplastic cells with a syncytial appearance. The cells are monotonous but have a stippled intermediate chromatin pattern with multiple small nucleoli. On the aspirate **(C)**, the Burkitt cells have an intermediate size, a denser chromatin than lymphoblasts, and deeply blue cytoplasm with prominent vacuoles.

intrathecal prophylaxis. In the United States, commonly used regimens include CODOX-M/IVAC, CALGB 9251, and hyper-CVAD. With these regimens, approximately 80% achieve CR, and 2-year survival is around 60% to 70%. In the CALGB 9251 trial, 52% of the patients were alive and in continuous CR at a median follow-up of 5.1 years. Because Burkitt lymphoma/leukemia has a predisposition for CNS involvement, aggressive CNS-directed therapy is essential and typically consists of intrathecal administration of methotrexate, cytarabine, and hydrocortisone. Recurrence after the first 2 years rarely occurs; therefore, maintenance therapy has not been shown to be beneficial and is not recommended.

Because of the strong expression of CD20 in mature B-cell ALL, several groups have incorporated rituximab into the frontline chemotherapy regimen with impressive further improvements in survival. The hyper-CVAD–rituximab regimen was reported in 31 patients with newly diagnosed Burkitt lymphoma/leukemia with a CR rate of 86% and a 3-year survival rate of 89%. Similarly, the addition of rituximab to the treatment in both the GMALL and CALGB regimens has proven feasible with OS of 91% (3 years) and 79% (2 years), respectively. Based on these exciting improvements in survival, the addition of anti-CD20 targeting to frontline therapies for BL is now considered the standard of care.

ADOLESCENTS AND YOUNG ADULTS WITH ALL: THE INTERSECTION BETWEEN PEDIATRIC AND ADULT ONCOLOGY

Evaluation of the outcomes of young adult patients, here defined as patients between the ages of 15 and 21 years old, presents specific challenges. Because of community referral patterns, these patients may be treated by either pediatric or adult oncologists. As such, the treating physician may view a patient in this age group either as an older child or as a younger adult. The oncologist will choose a regimen most appropriate for the population usually seen by that particular physician. A number of comparisons of the clinical outcome of adolescents enrolled on adult and pediatric clinical trials (Table 65-10) have resulted in interesting observations about what that appropriate treatment regimen should be and have guided the design of a number of prospective clinical trials designed specifically for AYAs with ALL.

Retrospective Comparison of Pediatric and Adult Cooperative Group Trials in Adolescents and Young Adults

The retrospective comparisons summarized in Table 65-10 were performed by large cooperative groups throughout the world and examined the outcome of the AYA patients treated on pediatric or adult cooperative group trials in ALL that were conducted contemporaneously. The majority of these retrospective comparison studies demonstrated a significant survival advantage for AYA patients treated by the pediatric versus the adult cooperative group. The first of these trials to have been reported highlights many of the interesting questions posed by these comparisons and is reviewed briefly below. The CALGB and the Children's Cancer Group (CCG) examined the outcome of 321 AYA patients between 16 and 20 years of age treated on consecutive trials from 1988 to 2001. The two patient groups were well matched for biologic features, including immunophenotype and cytogenetics. Although the age range was the same in both groups examined, the median age of the patients in the CALGB studies was 19 years compared with 16 years for the CCG patients. CR rates were identical—90% for both CALGB and CCG AYAs. However, CCG AYAs had a 63% EFS at 7 years and 67% OS at 7 years in contrast to the CALGB AYAs, in which 7-year EFS was only 34%. A difference in pattern of relapse was also noted. The incidence of CNS relapses was significantly higher in CALGB AYAs (11%) compared with the CCG AYAs (1.4%) ($P < .001$).

Table 65-10 Retrospective Comparison of Trials Involving Adolescent and Young Adult Acute Lymphoblastic Leukemia Patients

Trial Comparison	AYA Patients/ Median Age (Years)	CR Rate (%)	Survival Rate
United States			(7-year OS)
CALGB (adult)	124/19	90	46%
CCG (pediatric)	197/16	90	67%
France			(5-year EFS)
LALA-94 (adult)	100/18	83	41%
FRALLE-93 (pediatric)	77/16	94	67%
The Netherlands			(5-year EFS)
HOVON (adult)	73/20	91	38%
DCOG (pediatric)	47/12	98	71%
Italy			(2-year OS)

ALL97 (Pediatric)	61/NA	98	71%
Sweden			(5-year OS)
Adult ALL Group (adult)	99/18	90	39%
NOPHO-92 (pediatric)	36/16	99	74%
Finland			(5-year OS)
Finnish Leukemia (adult)	97/19	97	60%
NOPHO (pediatric)	128/13	96	67%

ALL, Acute lymphoblastic leukemia; *AYA,* adolescent and young adult; *CR,* complete remission; *EFS,* event-free survival; *NA,* not applicable; *OS,* overall survival.

Since the initial report of these findings in 2000, multiple national European cooperative groups have reported similar results with improvement in the outcome of AYAs treated on pediatric compared with adult protocols, and these are summarized in Table 65-10. Although the treatment approaches differ among countries, several treatment themes have emerged as being potentially important. Pediatric studies throughout the world use considerably more treatment with nonmyelosuppressive drugs, including glucocorticoids (both dexamethasone and prednisone), vincristine, and L-asparaginase. CNS prophylaxis is typically administered earlier, with a greater frequency and for a more prolonged period during pediatric group trials. Finally, long-term maintenance therapy was also continued for a longer period in pediatric cooperative group trials. Based on additional retrospective data from Finland and the MD Anderson Cancer Center, it appears that treating patients in a uniform fashion by an experienced group of physicians and nurses is also a very important component in the successful treatment of young adults with ALL.

To begin to address the many unanswered questions that have been raised by the retrospective comparison trials and to determine whether AYA patients treated by adult hematologists and oncologists can achieve similarly improved outcomes to the pediatricians for this age group, prospective cooperative group trials are being conducted in North America and in Europe. Early results from several of these trials have recently been reported. The PETHEMA Protocol ALL-96 addressed the toxicity and results of a pediatric-based protocol in 35 adolescent (ages 15-18 years) and 46 young adults (ages 19-30 years) with SR ALL. In this trial, patients received a standard five-drug, 5-week induction course followed by two cycles of early

consolidation, maintenance with monthly reinforcement cycles for 1 year after remission, and standard maintenance chemotherapy for up to 2 years after CR. The AYAs were well-matched for pretreatment characteristics. The CR rate was 98%, and with median follow-up of 4.2 years, the 6-year EFS and OS were 61% and 69%, respectively. The only significant predictor of poor EFS for the entire group was a slow response to initial induction therapy (>10% blasts remaining in BM aspirate done on day 14 of induction therapy). Thus, the investigators concluded that a pediatric regimen was tolerable and efficacious in AYAs with ALL up to the age of 30 years.

Two pilot studies from French adult cooperative groups have also demonstrated the feasibility of using modified pediatric-inspired regimens in adults with ALL, but the age range of these studies extends well into the middle years of adult life. In the French Acute Lymphoblastic Leukemia Pediatric group (FRALLE) study, 28 Ph^- adult ALL patients 16 to 57 years old were treated on the FRALLE 2000 protocol consisting of a prednisone prophase, four-drug induction including L-asparaginase, consolidation, delayed intensification, and maintenance chemotherapy. Four-year DFS was 90% versus 47% seen in matched historical control participants. In the Group for Research in Adult Acute Lymphoblastic Leukemia (GRAALL)- 2003 study, 225 patients with Ph^- ALL 15 to 60 years old (median, 31 years) were treated between 2003 and 2005 with five-drug induction, dose-intense consolidation, delayed intensification, and 2-year maintenance therapy. Notably, aSCT for patients younger than 55 years was recommended in this trial and makes interpretation of this trial more problematic. The CR rate was 93.5%. Among the 139 CR patients, 71 actually underwent transplantation in CR1 and were censored at the time of transplant. At 42 months, EFS was 55% versus 41% when comparing patients from an earlier French trial, the LALA-94, and the OS was 61%, significantly better than 41% the OS in the LALA-94 ($P < .001$). The benefit of the GRAALL approach was not statistically significant in patients older than 45 years of age because of a significant increase in treatment-related mortality of 23% compared with 5% TRM for patients younger than 45 years old. The investigators concluded that the use of a pediatric inspired regimen in adults up to 45 years old was tolerable and markedly improved outcome for "younger" adults with ALL. This regimen included older adults up to the age of 60 years and used only a modified pediatric regimen that did not use the dose intensity of corticosteroids, asparaginase, and vincristine that are routinely used in current pediatric regimens. Another difference from the pediatric regimens is that all patients in these trials still received prophylactic cranial irradiation. Also, the majority of CR1 patients actually underwent aSCT, which is not the approach used by pediatric groups. Thus, any interpretation of the contribution of the "chemotherapy" intensification component of these trials to DFS is very difficult. The Dana-Farber Cancer Institute consortium has also extended its successful pediatric regimen to older patients 18 to 50 years old. The trial design here was a true pediatric approach with intensification of *Escherichia coli* L-asparaginase, glucocorticoids, and vincristine for patients up to 50 years old; aSCT was not routinely recommended. Early results from this completed phase II trial have recently been presented. Ninety-four patients were evaluable, with a median age of 28 years (range, 18-50). Seventy-nine patients (84%) achieved a CR after 1 month of intensive induction therapy. With a median follow-up time of 45 months, the group reports an estimated DFS rate for all patients of 66% and OS rate of 65%. For the 74 patients with Ph^- ALL, DFS was 70%, and OS was 68%.

The largest prospective trial to evaluate the feasibility of using a pediatric regimen in AYA patients treated by adult medical hematologists and oncologists is ongoing in North America (CALGB-10403). The U.S. adult and pediatric cooperative groups are currently enrolling a total of 300 young adults 16 to 39 years old on a prospective phase II trial (CALGB-10403) that uses one treatment arm of a successful Children's Oncology Group (COG) protocol for adolescents (and HR children with ALL).

These prospective trials are demonstrating that it is possible to achieve significant improvements in outcome for AYAs with ALL, although many challenges remain to ensure access to care, to minimize treatment toxicity, and to develop and follow specific survivorship monitoring plans. The next generation of studies, linked to important biologic, psychosocial, and pharmacologic correlates, will result in further insights into optimizing the comprehensive approach to treatment and follow-up for this significant group of patients with ALL and may be the next step to achieving the high cure rate and successful transition back to "normal" life now routinely achieved in children with ALL. One of the other important issues that is beginning to be addressed in prospective trials is if these pediatric regimens can improve outcome for young adults, up to what age can this type of therapy be safely and successfully delivered?

OLDER ADULTS WITH ACUTE LYMPHOBLASTIC LEUKEMIA

Older adults (generally defined as older than 60 years old) constitute a challenging subset of ALL patients with worse prognosis reported in many studies compared with their younger counterparts. Most studies demonstrate that adults older than 60 years old have survival rates below 15%. Various factors contribute to the poor outcome of these patients, both patient related (e.g., the presence of comorbidities, less likely to be eligible for aSCT, poor tolerance of intensive chemotherapies) and disease related (more likely to have unfavorable disease characteristics such as the presence of Philadelphia chromosome). It is important to note that many large clinical trials have excluded patients older than 60 years of age; therefore, clinical outcome data for this group are sparse. Annino and colleagues reviewed results of 679 elderly patients (variably defined as older than 50 to older than 65 years of age, depending on the study) from 19 studies and reported a CR rate of 59% (range, 31%-85%) with an early mortality rate of 23% (range, 7.5%-50%) and 2-year OS of 15% to 19%, all of which are inferior to younger ALL patients. With hyper-CVAD regimens, the CR rate and 3-year survival for patients 60 years old or older ($n = 58$) were 88% and 29%, respectively. In a pooled analysis of six consecutive CALGB clinical trials, the CR rate and 3-year survival for patients 60 years old or older ($n = 197$) were 61% and 15%, respectively.

Sancho and colleagues reported results of the Spanish PETHEMA-ALL 96 trial looking specifically at the outcomes of Ph^- ALL patients who were 55 years of age or older. They initially treated 10 patients with an induction regimen consisting of vincristine, daunorubicin, prednisone, asparaginase, and cyclophosphamide. However, 7 of the 10 patients died during induction. Asparaginase and cyclophosphamide were then omitted from the induction cycle, and 23 additional patients were treated with a CR rate of 70%; the induction death rate was reduced to 22%. The 2-year DFS and OS for the entire series were 46% and 39%, respectively.

Because most patients in this age group may not be eligible for conventional myeloablative aSCT, consideration should be given for RIC-based aSCT. Initial results with the use of RIC conditioning have been favorable, and long-term data are awaited (see earlier section on allogeneic stem cell transplant).

Many novel agents are being evaluated for this group of patients given poor prognosis with the currently available therapies. The GRAALL-SA1 randomized phase II trial compared the efficacy and toxicity of pegylated liposomal doxorubicin (Peg-Dox) versus continuous-infusion doxorubicin (CI-Dox) in patients 55 years of age and older with Ph^- ALL patients. Use of Peg-Dox led to significant lower toxicities; however, there was a trend toward a lower CR rate, more refractory disease, and higher relapse rate in the Peg-Dox arm compared with CI-Dox arm. Other novel therapies are detailed in the Novel Therapies section later, and consideration should be given to incorporation of any promising agents into frontline therapies for older patients given the lack of progress with dose intensification of traditional agents. Management of elderly patients with Ph^+ ALL is discussed in the Ph^+ ALL section; the incorporation of TKIs into frontline therapy has already made significant improvements in DFS for these high-risk patients.

RELAPSED ACUTE LYMPHOBLASTIC LEUKEMIA

As described earlier, with standard therapies for ALL, long-term DFS is only around 30% to 40%. Thus, the majority patients with ALL relapse despite the administration of postremission treatment. Postrelapse therapies will lead to a second CR (CR2) in 30% to 40% of patients with a 5-year OS of only around 10%. An aSCT is the only chance for long-term cure in these patients and must be considered for all patients.

In the largest report of relapsed adult ALL patients to date, Fielding and colleagues analyzed the outcomes of relapsed adult ALL patients who were treated in the MRC UKALLXII/ECOG E2993 trial. Of the 1508 evaluable patients, 1372 (91%) achieved CR1, of whom 609 (44% of the CR1 patients) relapsed at a median of 11 months. The 5-year OS was only 7% for the relapsed patients, which was significantly worse compared with 38% for the newly diagnosed ALL patients in this study. The median OS for the relapsed patients was 5.5 months. The site of the relapses were BM alone (86%), CNS alone (4%), BM plus CNS (5%), and other extramedullary sites (4%). The majority of the relapses (81%) occurred within 2 years of diagnosis. In this series, none of the 55 patients who had CNS involvement at relapse were alive at 5 years. Receiving aSCT after relapse led to significant improved outcomes compared with chemotherapy alone (5-year OS, 23% for matched sibling SCT vs. 4% for the chemotherapy-alone arm).

Tavernier and colleagues reported outcomes of 421 ALL patients who experienced first relapse treated on the French LALA-94 trial. A CR2 was achieved in 44% patients with a median DFS of 5.2 months and median OS of 6.3 months. Factors associated with favorable outcome after relapse included transplant performed in CR2, CR1 of longer than 1 year's duration, and platelet count greater than 100,000/μL at relapse. The outcomes after relapse were not influenced by risk stratification at diagnosis or the treatment received during first CR. An aSCT was performed in 24% ($n = 99$) of the relapsing patients (in CR2 [$n = 61$] or with active disease at the time of SCT [$n = 38$], directly as a salvage therapy after relapse [$n = 14$], or after failure of salvage regimen [$n = 24$]). Median OS from an aSCT was 6.7 months with 5-year OS of 25% with a significantly higher OS at 3 years after aSCT in CR2 compared with those with active disease at the time of SCT.

Oriol and colleagues reported the outcomes of 263 ALL patients in first relapse treated in four consecutive PETHEMA trials. CR2 was achieved in 45% of patients, a rate similar to that in the French LALA trials. The median OS after relapse was 4.5 months with a 5-year OS of 10%. Factors associated with a favorable outcome after relapse included age younger than 30 years and CR1 duration of longer than 2 years. The best subgroup of patients was younger than 30 years old with CR1 longer than 2 years in which the 5-year DFS and OS were 53% and 38%, respectively.

Thus, patients with relapsed ALL continue to be a challenging subgroup of patients, and novel therapies (see later discussion) may improve outcomes by improving CR2 rates and increasing the percentage of patients who could be candidates for aSCT.

NOVEL THERAPIES

Many new agents are being investigated for patients with ALL, both in the relapsed and frontline setting. Clofarabine is a purine nucleoside analog that is currently approved by the United States FDA for the treatment of pediatric patients with relapsed or refractory ALL who have failed two prior regimens. The response rate CR, CR with incomplete recovery of platelets [CRp], and partial response [PR]) for this group of patients is approximately 30%. There are emerging data on the use of clofarabine in adults with relapsed or refractory ALL. Kantarjian and colleagues reported 17% response rate (CR, CRp, PR) with single-agent clofarabine in adults with relapsed or refractory ALL. Based on the modest single-agent activity, studies evaluating the role of the combination of clofarabine with cytarabine or cyclophosphamide are being conducted. The Southwest Oncology Group Study S0530 was a phase 2 trial of a combination of clofarabine and cytarabine for relapsed or refractory ALL patients ($n = 37$) and demonstrated a response rate of 17% (CR/CRp), which was not better than that reported as a single agent. Clofarabine has also been studied as a "bridge" to an aSCT in which the goal is to use clofarabine to provide adequate cytoreduction before an aSCT. The COG is now testing the addition of clofarabine to frontline therapy in an attempt to improve the outcomes for high-risk children and adolescents.

Nelarabine is a prodrug, which is demethylated by adenosine deaminase to the deoxyguanosine analog (ara-G). T lymphoblasts are sensitive to the cytotoxic effects of nelarabine, and this drug has been studied in T-cell ALL in the relapsed or refractory setting. DeAngelo and colleagues treated 26 patients with T-cell ALL and 13 patients with T-cell lymphoblastic lymphoma with nelarabine. The median age was 34 years (range, 16-66 years). The CR rate was 31% with a 1-year OS of 28%. Neurotoxicity was seen in many patients. Nelarabine is currently approved in the United States for both pediatric and adult patients with T-cell ALL and T-cell lymphoblastic lymphoma who have failed at least two chemotherapeutic regimens. The COG is currently testing the addition of nelarabine in frontline setting for T-ALL. The U.S. Intergroup and GMALL also have such trials in the planning stage.

Vincristine is an important component of ALL treatment. In preclinical models, encapsulation of vincristine into sphingomyelin liposomes or "sphingosomes" has been shown to lead to increased efficacy without increased neurotoxicity compared with conventional vincristine. A phase II trial of single-agent sphingosomal vincristine (2.0 mg/m^2 every 2 weeks) in 16 patients with relapsed or refractory ALL reported an overall response rate of 14%. A weekly schedule has also been evaluated in a phase I study in 36 relapsed or refractory ALL patients with a maximum tolerated dose of 2.25 mg/m^2/wk. Dexamethasone (40 mg) was given on days 1 to 4 and on days 11 to 14 of each 4-week cycle. The CR rate was 19% overall; it was 29% for those who underwent therapy as their first salvage treatment. Based on these results, an international phase III trial has been initiated to examine the benefit of the liposomal vincristine in frontline therapy of older adults with ALL.

L-asparaginase (asparaginase) is an important component of ALL therapy and has been incorporated into most ALL trials. ALL cells are unable to produce asparagine and are dependent on plasma levels of this amino acid for protein synthesis. Depletion of asparagine results in inhibition of protein synthesis and subsequent apoptotic leukemic cell death. Traditionally, native enzyme derived from *E. coli* has been used. However, this preparation can be immunogenic, leading to hypersensitive reactions and development of cross-reacting antibodies. Polyethylene glycosylated (PEG)–asparaginase, formed by covalently attaching polyethylene glycol to the native *E. coli* enzyme, has been developed and offers lower immunogenicity and a longer half-life. Douer and colleagues treated 25 newly diagnosed adult ALL patients (median age, 27 years; range, 17-55 years) with the adult ALL BFM protocol in which 14 injections of *E. coli* asparaginase were replaced by a single dose of pegaspargase (2000 IU/m^2 IV) on day 16 of induction therapy. After the single dose, asparagine deamination was complete in all patients after 2 hours and in 100%, 81%, and 44% on days 14, 21, and 28, respectively. No allergic reactions or pancreatitis was observed, and a CR was achieved in 24 of the 25 patients. The CALGB 9511 trial used pegaspargase (2000 IU/m^2 subcutaneously, two doses during induction and two during first intensification) as part of the five-drug induction regimen. Of the 85 evaluable patients, those with effective asparagine depletion (defined by enzyme levels >0.03 U/mL plasma for 14 consecutive days after pegaspargase administration) had improved DFS and OS compared with those without effective asparagine deletion. Thus, use of pegaspargase appears safe and effective in adults, and it may replace native L-asparaginase as the agent for asparagine deletion. To avoid systemic toxicities, a novel preparation of L-asparaginase in which L-asparaginase is encapsulated within red blood cells (GRASPA) has been developed and is in early phase testing in Europe.

TARGETED AGENTS

Given the established role of rituximab in many lymphoid malignancies, including BL (as described earlier), a similar approach has recently been tested in precursor B-cell ALL. Studies have shown that up to 20% to 40% pre-B ALL express CD20 (≥20% leukemia cells positive). In a retrospective analysis, the MD Anderson group reported the poor prognostic value of CD20 expression in adult precursor B-cell ALL. They subsequently incorporated rituximab into a modified hyper-CVAD regimen for patients with CD20 expression of 20% or greater. When analyzing the younger cohort of patients (younger than 60 years of age), incorporation of rituximab led to very significant improvement in 3-year OS of 75% compared with 47% in historical control participants ($P = .003$). In this study, the addition of rituximab did not improve the outcomes of patients older than 60 years old. The GMALL has substantiated these results.

CD22 is a commonly expressed antigen on the precursor B-cell lymphoblasts and therefore represents an attractive target. Epratuzumab, a humanized monoclonal antibody against CD22, has also activity in a subset of patients with ALL. In a COG pilot study, epratuzumab in combination with standard reinduction chemotherapy was evaluated in 15 pediatric patients with relapsed ALL. There was rapid clearing of surface CD22 antigen, and 9 of 15 patients achieved a CR. More recently, a conjugated anti-CD22 antibody has been introduced with promising results. Inotuzumab ozogamicin, a CD22 monoclonal antibody attached to immunotoxin calicheamicin, has shown activity in non-Hodgkin lymphoma and is currently being evaluated in ALL patients. In a preliminary report, 49 relapsed or refractory ALL patients were treated with inotuzumab IV on an every-3-week schedule. The drug was well tolerated with an overall response rate of 57% in patients with relapsed or refractory ALL. Additional phase I studies to determine the optimal dose and schedule of inotuzumab are underway. Moxetumomab pasudotox is a recombinant immunotoxin composed of the variable domain of anti-CD22 monoclonal antibody fused to a truncated form of *Pseudomonas* exotoxin A. In a phase I, dose-escalation study, 21 pediatric patients with relapsed or refractory ALL were enrolled. The drug was well tolerated. In this heavily pretreated patient population (median number of prior therapies, four), preliminary efficacy results are encouraging with hematologic improvement in 41% and CR in 24% of the patients.

Blinatumomab is a novel antibody (BiTE antibody) designed to engage the patient's T cells to CD19-expressing target B cells, resulting in a cytotoxic T-cell response. Preliminary results of an exploratory phase II trial of single-agent blinatumomab in adult patients with relapsed or refractory precursor-B ALL were recently reported. Blinatumomab was administered by continuous IV infusion for 28 days followed by a 14-day rest. Responding patients could proceed to an aSCT or receive up to total of 5 cycles of blinatumomab. Of the 18 evaluable patients, 12 achieved CR with a CR rate of 67%. All CR patients achieved MRD negativity by the second cycle. These data are particularly encouraging because a CR rate of 67% in the relapsed or refractory setting with a single-agent therapy is unprecedented, and responses appear to be durable. Incorporation of blinatumomab into the frontline therapy is planned by the U.S. Intergroup.

Because approximately 70% of all (both precursor B-cell and precursor T-cell) ALL patients express CD52, alemtuzumab, a humanized anti-CD52 monoclonal antibody, has been evaluated in ALL as an agent for eradication of MRD during postremission therapy. In a phase I/II study (CALGB 10102), dose escalation of alemtuzumab was tested in 24 $CD52^+$ ALL patients in CR1 in which it was given to a target dose of 30 mg administered subcutaneously three times a week for 4 weeks during postremission therapy. Serial assessment of MRD using clone-specific PCR was possible in 11 of 24 cases, and a median 1-log decrease in MRD was noted in the 20- and 30-mg cohorts. Alemtuzumab, as a single agent, has limited activity in relapsed or refractory pediatric and adult ALL. A combination of alemtuzumab and rituximab has recently been shown to lead to promising results in a NOD/SCID (nonobese nondiabetic/severe combined immune deficient) mouse model and should pave way for clinical trials exploring such an approach.

Ponatinib, an oral multiple TKI, is a potent pan–BCR-ABL inhibitor with activity against all tested imatinib-resistant mutants, including T315I. A dose-escalation phase I trial was recently reported, and 45 mg once daily was selected as a phase II dose. Preliminary results are very encouraging, especially in T315I mutant patients in whom all first- and second-generation TKIs are ineffective. Initial results from the pivotal phase 2 study of ponatinib (Ponatinib Ph+ ALL and CML Evaluation [PACE] trial) were recently reported. In the chronic myeloid leukemia blast phase/Ph^+ ALL cohort, 11 of the 30 (37%) patients who were resistant or intolerant to second-generation TKIs and 6 of the 22 (27%) patients with T315I mutations achieved a major hematologic remission. Other BCR-ABL kinase inhibitors such as bosutinib and INNO-406 and aurora kinase inhibitors such as MK-0457 have also been evaluated in Ph^+ ALL.

There has been an increasing understanding of the molecular biology of ALL, which may translate into newer therapeutic options. Mullighan and colleagues reported loss of the *IKZF1* gene on 7p12, which encodes the early lymphoid transcription factor Ikaros in 84% of BCR-ABL–positive ALL and in 28% of BCR-ABL–negative B-cell ALL. An *IKZF1* deletion was reported in 63% of 83 adult Ph^+ ALL patients treated in various GIMEMA trials. The presence of deletion of the *IKZF1* gene has been associated with poor prognosis with worse DFS and increased relapse risk. Patients with IKZF1 alteration have a gene expression profile similar to that of Ph^+ ALL, and one-third of such patients have rearrangements of the lymphoid cytokine receptor gene *CRLF2,* either alone or with mutations of the Janus kinase (JAK) genes *JAK1* and *JAK2*. This provides rationale to test JAK inhibitors as a targeted strategy for this group of patients.

NOTCH1 activation occurs in more than 50% of patients with precursor T-cell ALL and has been used as a therapeutic target. γ-Secretase is required for *NOTCH1* proteolytic activation, and small molecule γ-secretase inhibitors are being been tested in early phase clinical trials. Targeting the mTOR (mammalian target of rapamycin) pathway has also been studied both for patients with NOTCH1 activation and in other subsets of ALL patients.

AMD11070 is an orally available, small molecule inhibitor of CXCR4 and has been studied in ALL cell lines and mouse models as an agent to eradicate leukemic cells that are otherwise protected by stromal elements. Mice with murine Ph^+ ALL survived significantly longer when treated with a combination of nilotinib and AMD11070. Similarly, combination of vincristine and AMD11070 showed encouraging responses.

SURVIVORSHIP

Although fewer specific data are available on long-term complications of survivors of young adults with ALL, the long-term complications of successful treatment of children with ALL have been well described and include neurocognitive and neurologic dysfunction, endocrine and metabolic abnormalities (including obesity), bone toxicity (osteonecrosis), cardiac toxicity, and secondary malignancies. To guide the frequency and focus of medical visits and the ordering of appropriate surveillance tests, comprehensive guidelines have been published in many countries, including North America, where guidelines created by the COG, titled "Long-Term Follow-up Guidelines for Survivors of Childhood, Adolescent and Young Adult Cancers" are available at http://www.survivorshipguidelines.org and should be adopted by the adult oncology community.

FUTURE DIRECTIONS

Acute lymphoblastic leukemia is a heterogeneous group of diseases with varied clinical outcomes, depending on molecular, cytogenetic, and clinical characterization. There have been significant advances in our understanding of the molecular pathogenesis of this disease,

which should translate into effective targeted therapies and better patient outcomes. Given the rarity of this disease, it is strongly recommended that patients are referred to centers of expertise, and it is crucial that patients be enrolled in clinical trials designed to evaluate subset-specific therapies to improve survival.

CHAPTER 66

CHRONIC MYELOID LEUKEMIA

Ravi Bhatia

Chronic myeloid leukemia (CML) is a hematopoietic malignancy originating from transformation of a primitive hematopoietic cell. Without treatment, CML progresses from an initial chronic phase (CP) characterized by marrow hyperplasia and increased numbers of circulating differentiated myeloid cells followed by advanced phases of disease (accelerated phase [AP] and blast crisis [BC]) marked by a block in differentiation, an accumulation of blasts, and a depletion of normal hematopoietic cells, especially white blood cells and platelets. CML was the first malignant disease found to be consistently associated with a specific cytogenetic abnormality, the Philadelphia chromosome (Ph), resulting in the formation of the BCR-ABL fusion oncogene. Study of BCR-ABL has led to sensitive methods to detect residual disease and predict outcome and to "targeted" therapy aimed at inhibiting abnormal tyrosine kinase activity resulting from the BCR-ABL fusion oncogene. In addition, CML was one of the first diseases demonstrated to be curable by hematopoietic cell transplantation (HCT). Thus CML has become the model for "tailored" therapy, in which various treatments can be escalated on the basis of molecular response.

ETIOLOGY/EPIDEMIOLOGY/GENETICS

Chronic myelogenous leukemia was recognized as a distinct entity, associated with massive splenomegaly and leukocytosis without other explanations, in the mid-1800s. The modern history of CML was initiated by Nowell and Hungerford in 1960. They used newly developed techniques to detect a small chromosome in metaphase preparations of marrow cells from CML patients. This abnormal chromosome was the first consistent chromosomal abnormality in human malignancies and was termed the *Philadelphia chromosome* after the city of its discovery. Rowley showed that the Philadelphia chromosome resulted from a translocation between chromosomes 9 and 22 [t(9;22)(q34;q11)] (Fig. 66-1). The genes involved in this translocation were cloned in the 1980s, and the t(9;22) translocation was shown to result from the fusion of the BCR (breakpoint cluster region) gene on chromosome 22 to the (Abelson leukemia virus) gene on chromosome 9, with formation of the BCR-ABL fusion oncogene. This oncogene codes for a constitutively active cytoplasmic tyrosine kinase, which is now believed to be the principal cause of the chronic phase of CML. Until the 1970s, CML was regarded as an incurable and inevitably lethal disorder. It was then recognized that selected patients can be cured, by allogeneic HCT. However, transplantation therapy for CML is limited by donor availability and the risk for life-threatening toxicity. More recently, imatinib mesylate and other tyrosine kinase inhibitors (TKIs) that specifically block the enzymatic action of the abnormal tyrosine kinase coded by the fusion oncogene have resulted in a high rate of remission and improved survival in CML patients.

Chronic myelogenous leukemia is the most common of the myeloproliferative diseases and represents 15% to 20% of all new leukemia cases. The annual incidence of CML is 1 to 1.5 cases per 100,000 population per year. The median age at diagnosis is 67 years and the incidence sharply rises with age. The disease occurs slightly more often in men than in women. Chronic myelogenous leukemia may occur in children, but only approximately 10% of cases occur in subjects between 5 and 20 years of age and represent only 3% of all childhood leukemias. Concordance of disease is not observed between identical twins. Radiation may play a role in some cases. Persons exposed to high-dose irradiation, including survivors of atomic bombing, have a significantly increased risk for leukemia. High-dose irradiation of myeloid cell lines in vitro induces the expression of BCR-ABL transcripts indistinguishable from those that characterize CML. The BCR-ABL gene can be detected at very low levels in a proportion of healthy individuals using a very sensitive PCR assay. These findings suggest that the fusion gene develops relatively frequently in hematopoietic cells, but only infrequently lead to leukemia development. The mechanism by which the Ph chromosome is first formed and the time required for progression to overt disease are unknown.

PATHOPHYSIOLOGY

CML is generally believed to develop from transformation of a primitive hematopoietic stem cell (HSC) by the BCR-ABL fusion gene. The progeny of transformed HSC have a proliferative advantage over normal hematopoietic cells, thus allowing the Ph-positive clone gradually to displace residual normal hematopoiesis. The translocation is found in cells of myeloid, erythroid, megakaryocytic and B-lymphoid origin, consistent with a hematopoietic stem cell origin of the disease. Hematopoietic expansion in patients with chronic-phase disease primarily involves an increase in myeloid cell mass, related to an expansion of mature cells, as well as increased numbers of precursor and progenitor cells. In chronic phase, the leukemic cells are minimally invasive and are primarily located in hematopoietic tissues including blood, bone marrow, spleen, and liver. The proliferative advantage of the malignant clone may be related to enhanced responsiveness to hematopoietic growth factors and/or reduced response to inhibitory factors. Chronic myelogenous leukemia progenitors also demonstrate defective adhesion to marrow stromal cells and extracellular matrix. Altered microenvironmental interactions may contribute to another feature of CML, which is abnormal progenitor trafficking with increased numbers of circulating progenitors and extramedullary hematopoiesis. Several observations indicate that although the Ph-positive clone displaces normal hematopoiesis, it does not destroy residual normal stem cells. For example, Ph-negative progenitors can be seen after cultures of CML cells in vitro can be selected on the basis of cell surface phenotype, and can be identified in the blood after high-dose chemotherapy. As described later in the Therapy section, treatment with agents such as interferon (IFN) or tyrosine kinase inhibitors can result in restoration of Ph-negative hematopoiesis in CML patients.

The BCR-ABL gene results from a chromosomal translocation that results in the fusion of the ABL gene on chromosome 9 and the BCR gene on chromosome 22 (Fig. 66-2). The translocation is related to a break in ABL upstream of exon a2 and in the major breakpoint cluster region of the BCR gene. This leads to juxtaposition of a 5′ portion of BCR and a 3′ portion of ABL on a shortened chromosome 22 (the derivative 22q-, or Ph). The resulting messenger RNA (mRNA) usually contains one of two BCR-ABL junctions, designated e13a2 (formerly b2a2) and e14a2 (or b3a2). Both

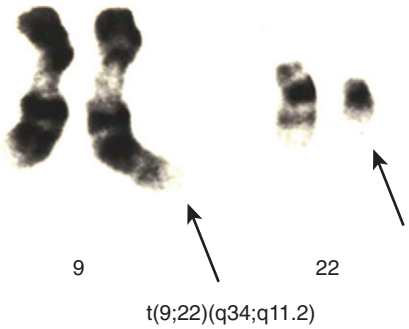

Figure 66-1 PARTIAL KARYOTYPE SHOWING THE t(9;22)(q34;q11). The Philadelphia chromosome is the derivative chromosome 22 *(right arrow).*

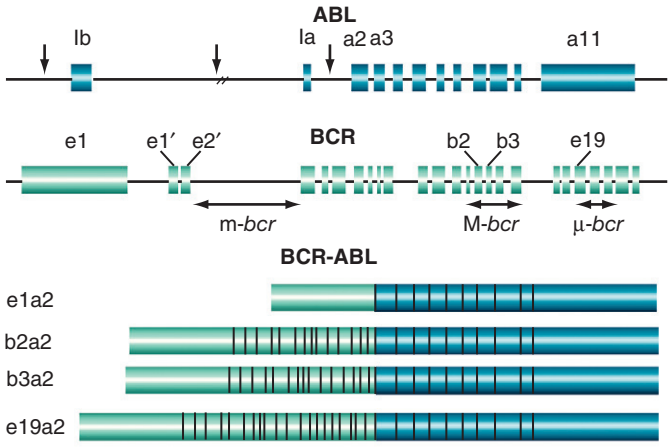

Figure 66-2 LOCATIONS OF THE BREAKPOINTS IN THE ABL AND BCR GENES AND STRUCTURE OF THE CHIMERIC mRNAs DERIVED FROM THE VARIOUS BREAKS. *(Modified from Deininger MW, Goldman JM, Melo JV, editors: The molecular biology of chronic myeloid leukemia,* Blood *96:3343, 2000.)*

BCR-ABL mRNA molecules are translated into a 210-kd fusion protein, referred to as *p210BCR-ABL*. Rarely, other variant breakpoints and fusions can give rise to full-length, functionally oncogenic BCR-ABL proteins, notably p190BCR-ABL (associated with an e1a2 mRNA junction) and p230BCR-ABL (associated with an e19a2 mRNA junction). Of patients with CML who have a normal-appearing karyotype, one-third have a cytogenetically occult BCR-ABL gene, usually located on a normal-appearing chromosome 22 but occasionally on chromosome 9. In the remaining patients with Ph-negative, BCR-ABL-negative disease, the molecular basis of leukemia is not known.

Some studies have suggested that pathogenesis of CML may be a multistep process, with development of clonal hematopoiesis preceding the t(9;22) translocation. However, there is substantial evidence to suggest that the generation of a classic BCR-ABL fusion gene in a hematopoietic stem cell is sufficient to initiate CML. Expression of BCR-ABL has been shown to transform mouse fibroblast cell lines, growth factor-dependent hematopoietic cell lines, and primary murine bone marrow cells. Expression of BCR-ABL in human $CD34^+$ cells also causes increased proliferation, reduced apoptosis, and altered adhesion and migration mimicking alterations seen in progenitor cells from CML patients. Transplantation of murine bone marrow cells made to ectopically express the BCR-ABL gene by retroviral transduction induces a myeloproliferative disorder (MPD) that closely resembles human CML with increased numbers of peripheral blood cells (with a predominance of granulocytes), splenomegaly, and extramedullary hematopoiesis, although the disease is much more fulminant than human CML. Initial development of transgenic and knock-in mouse models of CML was problematic. It appears to be crucial to express this oncogene in the proper cell type. Expression of BCR-ABL in B-cell lymphocytic and megakaryocytic precursors resulted in the development of B–acute lymphocytic leukemia (B-ALL) and megakaryocytic myeloproliferative syndrome. Specific expression of the oncogene in hematopoietic stem cells through a stem cell leukemia (SCL) enhancer to regulate expression induces development of a CML-like disease. Together, these studies indicate that BCR-ABL expression alone is sufficient to induce chronic-phase CML-like disease in mice.

The ABL gene encodes a nonreceptor tyrosine kinase that is expressed in most tissues (Fig. 66-3). Mice with homozygous disruption of the ABL gene demonstrate increased perinatal mortality, lymphopenia, and osteoporosis and are smaller, with abnormal head and eye development. The BCR gene also encodes a signaling protein that contains multiple modular domains (see Fig. 66-2). Although BCR-deficient mice develop normally, their neutrophils produce excess levels of oxygen metabolites following activation. The normally regulated tyrosine kinase activity of the ABL protein is constitutively activated by the juxtaposition of N-terminal BCR sequences. BCR acts by promoting protein dimerization, leading to phosphorylation of tyrosine residues in the kinase-activation loops and leading to constitutive activation of kinase activity. The fusion of BCR sequences to ABL also adds new regulatory domains/motifs to ABL, such as the growth factor receptor–bound protein 2 (GRB2) SH2-binding site. The uncontrolled kinase activity of BCR-ABL and enhanced interaction with a variety of effector proteins lead to deregulation of cell signaling mechanisms that regulate proliferation. The ABL protein is located in both the nucleus and the cytoplasm and shuttles between these two compartments, whereas the BCR-ABL is exclusively cytoplasmic and localizes to the cytoskeleton, where it appears to contribute to adhesion and migration abnormalities.

The structure of the BCR-ABL protein and the biochemical pathways affected have been extensively studied (see Fig. 66-3). However, most such interactions have been studied only in cell lines and conditions of forced overexpression. Their existence in primary leukemia cells and relevance to CML pathogenesis is not certain. The murine transduction-transplantation CML model has been helpful in studying the role of BCR-ABL domains and signaling interaction in primary hematopoietic cells. However, the murine CML model is not fully representative of human CML, and the role of different domains in development of disease in CML patients still needs to be confirmed. The ABL tyrosine kinase is crucial for oncogenic transformation. Mice that express a form of BCR-ABL with a point mutation in the ATP-binding site of ABL that inhibits its kinase activity do not develop leukemia. This suggests that the ABL kinase activity is essential for BCR-ABL leukemogenesis in vivo. The success of kinase inhibitor therapy for CML provides further proof of the importance of kinase activity in maintenance of human disease. Other important domains in BCR-ABL also regulate the kinase activity of ABL or connect to other downstream signaling pathways. The amino-terminal coiled-coil (CC) oligomerization domain of BCR is an important activator of ABL kinase activity, and also promotes the association of BCR-ABL with F-actin fibers. Phosphorylation of BCR at tyrosine 177 generates a GRB2-binding site, which is important for RAS activation. Mutation of the tyrosine-177 residue of BCR-ABL to phenylalanine (Y177F) largely abolishes its ability to bind GRB2, without affecting the kinase activity of ABL. The Y177F mutant has a greatly reduced ability to induce MPD in mice. A tyrosine phosphorylation site in the activation loop of the ABL kinase domain and the SH2 domain of ABL also contribute to RAS activation. Mutations in the SH2 domain of ABL and a Y1294F point mutation reduce the ability of BCR-ABL to induce a CML-like MPD in mice. The carboxy-terminal region of ABL is required for the proper function of normal ABL. However, deletion of the ABL actin-binding domain was reported to not affect the ability of BCR-ABL to induce CML-like MPD in mice, suggesting that this domain may be dispensable for BCR-ABL–mediated leukemogenesis. Certain BCR-ABL domains may have complementary or overlapping functions.

Many signaling proteins become phosphorylated in BCR-ABL–expressing cells and/or to interact with BCR-ABL through various

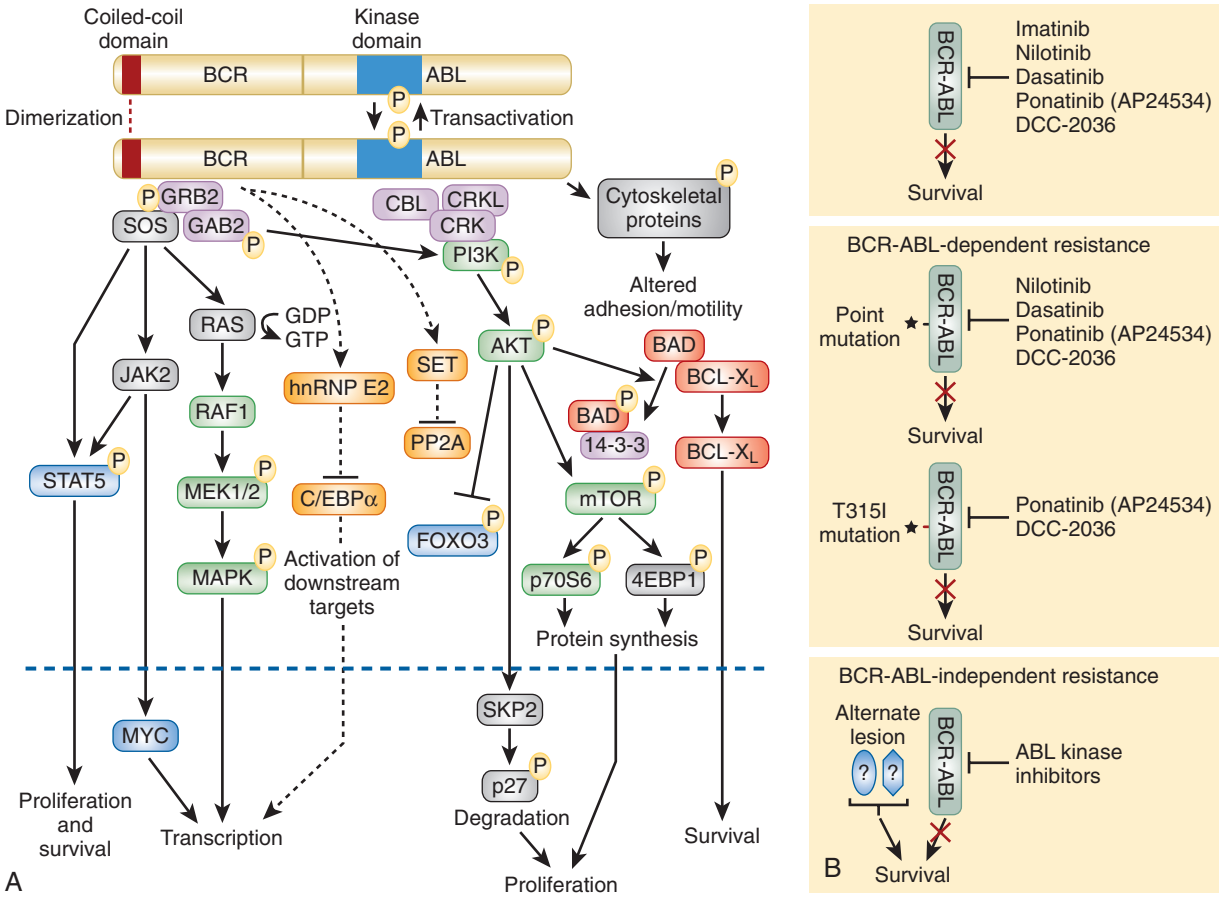

Figure 66-3 THE BCR-ABL SIGNALING NETWORK AND ABL KINASE INHIBITION. **A,** BCR-ABL signaling pathways activated in CML. Dimerization of BCR-ABL triggers autophosphorylation events that activate the kinase and generate docking sites for intermediary adapter proteins *(purple)* such as GRB2. BCR-ABL -dependent signaling facilitates activation of multiple downstream pathways that enforce enhanced survival, inhibition of apoptosis, and perturbation of cell adhesion and migration. A subset of these pathways and their constituent transcription factors *(blue)*, serine/threonine-specific kinases *(green)*, and apoptosisrelated proteins *(red)* are shown. A few pathways that were more recently implicated in CML stem cell maintenance and BCR-ABL -mediated disease transformation are shown *(orange)*. Of note, this is a simplified diagram and many more associations between BCR-ABL and signaling proteins have been reported. BCR-ABL is unstable upon disruption of primary CML cells; therefore, pharmacodynamic evaluation of BCR-ABL activity is performed by monitoring the tyrosine phosphorylation status of either CRKL or STAT5, with CRKL phosphorylation considered the most specific readout. **B,** Predicted effectiveness of ABL kinase inhibitors in three therapeutic scenarios: to inhibit native BCR-ABL *(top)*, to inhibit mutated BCR-ABL *(middle)*, and as a component in the control of CML involving a BCR-ABL -independent alternate lesion *(bottom)*. *(From O'Hare T, Deininger MWN, Eide CA, et al: Targeting the BCR-ABL signaling pathway in therapy-resistant Philadelphia chromosome-positive leukemia.* Clin Cancer Res *17:212, 2011.)*

functional domains. These interactions in turn activate signaling through mechanisms including RAS, PI3K, AKT, JNK, and SRC family kinases, protein phosphatase, STATs, nuclear factor-B, and MYC. BCR-ABL also induces expression of cytokines such as interleukin-3 (IL-3), granulocyte colony-stimulating factor (G-CSF), and granulocyte-macrophage colony-stimulating factor (GM-CSF). A CML-like MPD was still induced following expression of BCR-ABL in bone marrow cells from Stat5a$^{-/-}$Stat5b$^{-/-}$, Cbl$^{-/-}$, and Il-3$^{-/-}$GM-CSF$^{-/-}$ mice, indicating that these proteins may not be required for BCR-ABL-mediated leukemogenesis. BCR-ABL expression induced CML-like MPD but failed to induce B-ALL in mice that lacked the SRC family kinases LYN, HCK, and FGR, indicating the potential importance of the kinases in lymphoid blast crisis or ALL but not for MPD.

Progression to accelerated phase and blast crisis is associated with increase in immature blast cells that may be located within hematopoietic tissues or may infiltrate a number of extramedullary sites, including lymph nodes, skin, soft tissue, and the central nervous system. A number of molecular mechanisms, rather than a single gene defect, are likely to underlie the arrest of maturation, enhanced proliferation and survival, and increased tissue invasiveness that characterize blast crisis CML. Increased level of BCR-ABL expression is a common feature and appears to be a key factor in the development of features of blast crisis, through effects on cell signaling and on transcription and translation of important regulatory genes. Disease progression is related to susceptibility of the BCR-ABL-expressing clone to additional molecular changes. Additional cytogenetic and molecular changes are frequently seen during progression. Genetic instability in CML appears may be induced by several factors, including increased oxidative stress, reduced DNA repair, or reduced DNA damage checkpoint signaling response. Genetic changes observed in leukemic cells from blast-phase CML patients include nonrandom cytogenetic changes such as ++8, ++Ph, ++19, and I(17)q; point mutations in TP53, RB, and CDKN2A (p16^{INK4A}); and overexpression of EVI1 and MYC. Additional chromosome translocations are also observed, such as t(3;21)(q26;q22), which generates AML1-EVI1. Other CML-associated fusion genes include AML1-ETO, resulting from the t(8;21)(q22;q22) translocation; NUP98-HOXA9, resulting from the t(7;11)(p15;p15) translocation; and CBFβ-SMMHC, which results from inv(16)(p13;q22). These observations

suggest that the block in myeloid differentiation in blast crisis may involve cooperation between BCR-ABL and defects in hematopoietic transcriptional regulators. Gene expression analyses suggest that the progression of CML from CP to advanced phase is associated with gene expression changes occurring early in accelerated phase before the accumulation of increased numbers of leukemia blast cells. Especially noteworthy and potentially significant in the progression program are deregulation of the WNT/beta-catenin pathway, decreased expression of JUN B and FOS, and alternative kinase deregulation. Other studies suggest that the granulocyte/macrophage progenitor (GMP) pool is expanded in patients with blast-phase CML, and that these cells have increased levels of BCR-ABL expression and increased WNT signaling activity that may lead to increased self-renewal capacity, transforming GMP cells into leukemic stem cells.[1,2]

CLINICAL FEATURES

History

Most CML patients (>90%) present in chronic phase. CML is often diagnosed incidentally during routine examination or examination for another illness. Symptoms usually include fatigue, weight loss, bone pain, sweating, and abdominal discomfort and early satiety related to splenomegaly. Symptoms are generally gradual in onset over weeks to months. Uncommon presenting symptoms include those related to leukostasis, acute abdominal pain related to splenic infraction, priapism, and hypermetabolism, hyperuricemia, and gouty arthritis.

Physical Examination

Physical examination may detect pallor and splenomegaly. In the past, the incidence of splenomegaly was often greater than 90% at diagnosis, but this has been decreasing in frequency since the disease is being diagnosed earlier.

Laboratory Manifestations

Laboratory findings at presentation generally include leukocytosis, thrombocytosis, and anemia (Fig. 66-4). The total leukocyte count is always elevated at the time of diagnosis and is usually over 25×10^9/L. The WBC count rises progressively if patients are left untreated. Striking cyclic variations in WBC counts have been described in rare patients. Differential counts reveal granulocytes at all stages of differentiation in peripheral blood cells. Circulating granulocytes are usually normal in appearance. The blast percentage is between 0.5% and 10%. Neutrophil alkaline phosphatase activity is low or absent in more than 90% of patients. However, activity can increase in response to infection, inflammation, and reduction of counts by treatment. Functional abnormalities of neutrophils are mild and are not associated with predisposition to infection. Although the proportion of eosinophils is usually not increased, the absolute eosinophil count is usually increased. The absolute basophil count is almost always increased in CML. The proportion of basophils is usually less than 15% in chronic-phase patients, although rarely, this may be higher. In contrast to mastocytosis, hyperhistaminemia is uncommon. The absolute lymphocyte count is increased as a result of an increase in T but not B cells.

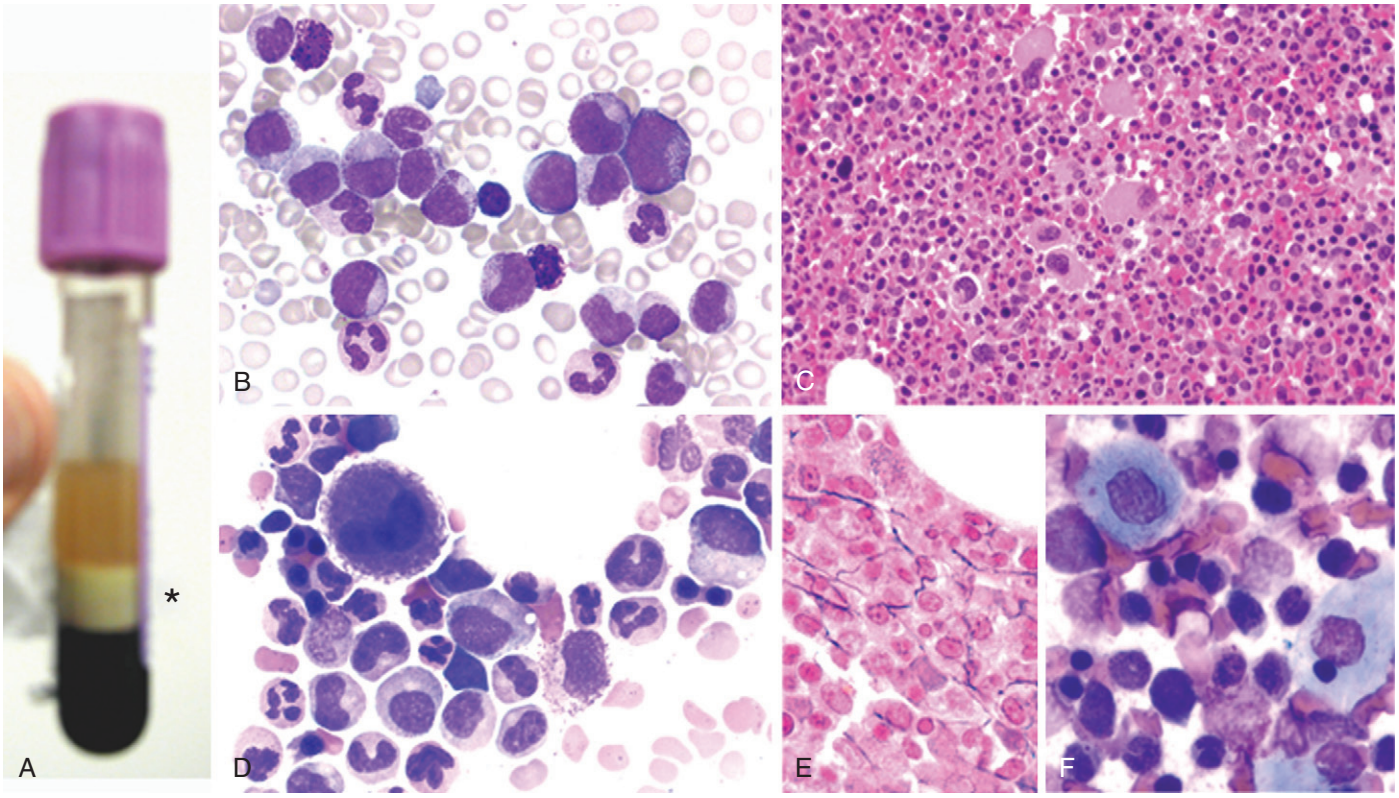

Figure 66-4 CHRONIC MYELOGENOUS LEUKEMIA, PERIPHERAL BLOOD TUBE, AND IMAGES OF BLOOD SMEAR AND BONE MARROW BIOPSY AND ASPIRATE IN CHRONIC PHASE. **A,** The spun tube of peripheral blood (EDTA collected) is from a patient with chronic phase CML who presented with a white blood cell count of about 600K/μL. Note the markedly expanded "buffy coat" layer *(asterisk)* due to the severe leukocytosis. **B,** Peripheral smear showing marked leukocytosis due to a granulocytic proliferation of all stages with particularly increased myelocytes and absolute basophilia. **C,** Bone core biopsy illustrating markedly hypercellular marrow due to granulocytic proliferation and increased small hypolobated megakaryocytes. **D,** Bone marrow aspirate showing the same granulocytic proliferation and small, "dwarf" megakaryocytes. Mild fibrosis as seen on reticulin stain **E,** and pseudo-Gaucher cells **(F).**

The platelet count is elevated in 50% of patients at the time of diagnosis. The platelet count may increase during the course of chronic phase. Platelet dysfunction may occur, but disorders of thrombosis and hemorrhage are rare. Thrombocytopenia is rare at diagnosis and usually is a sign of progression toward accelerated phase. A deficiency in the second wave of aggregation to epinephrine is the most common abnormality and is associated with deficiency of adenine nucleotides in the storage pool. The hematocrit is decreased in most patients at diagnosis. Red cells tend to show only mild alterations with increased variability of size and shape. Small numbers of nucleated red blood cells and mild reticulocytosis may be seen.

Chemical abnormalities seen in patients with untreated CML include hyperuricemia and hyperuricosuria. The formation of urate stones is common, and patients with underlying susceptibility may develop acute gouty arthritis or urate nephropathy. Patients have increased serum level of vitamin B_{12}–binding capacity related to release of transcobalamin I and II from mature neutrophils. The serum B_{12} level in CML is an average of 10-fold higher than normal. Serum LDH is elevated in CML. Pseudohyperkalemia may be seen related to release of potassium from WBC during clotting. Spurious hypoglycemia or hypoxemia may result from consumption by neutrophils after a sample is drawn.

Examination of the marrow usually reveals a very hypercellular marrow, with 75% to 90% marrow cellularity (see Fig. 66-4, *C-D*). The granulocytic-to-erythroid ratio is increased to 10:1 to 30:1, with increased granulopoiesis and reduced erythropoiesis. Eosinophils and basophils may be increased. Blasts usually represent less than 5% of cells. Presence of more than 10% blasts indicates transformation to accelerated phase. Megakaryocytes are typically smaller than usual and may have hypolobated nuclei. Megakaryocyte numbers may be normal or slightly decreased, but 40% to 50% of patients show moderate to extensive proliferation of megakaryocytes. Collagen type III detected by silver staining is typically increased (see Fig. 66-4, *E*). Approximately half of patients demonstrate increased reticulin fibrosis, which may be associated with increased megakaryocytes in marrow. Increased fibrosis may be associated with larger spleen size, anemia, and increased blasts in blood and marrow. Pseudo-Gaucher cells and sea blue histiocytes, secondary to increased marrow cell turnover, may be seen in 30% of specimens (see H5eC69, Fig. 66-4, *F*). The spleen shows enlargement related to infiltration of the cords of the red pulp with granulocytes at different stages of maturation. The liver may show infiltration with granulocytic cells in the portal areas and hepatic sinusoids.

Cytogenetic examination shows t(9;22)(q34;q11) and Ph chromosome in more than 90% of patients. Additional chromosomal abnormalities besides the Philadelphia chromosome are seen at diagnosis in 20% of patients including –Y and +8, and have not been shown to affect disease course. Variant Ph chromosomes are seen in 5% of patients, with complex rearrangement involving exchange of material with an additional chromosome besides chromosomes 9 and 22. In a small proportion of patients cryptic or complex translocations can be detected by fluorescence in situ hybridization (FISH) or polymerase chain reaction (PCR) assays. The methodology used for identifying BCR-ABL transcripts has evolved over the years. Initially it was possible only to identify the presence or absence of BCR-ABL transcripts by either single-step amplification or a two-step "nested" amplification with internal primers to increase the sensitivity. Real-time quantitative polymerase chain reaction (RQ-PCR) provides an accurate measure of the total leukemia cell mass, and the degree to which BCR-ABL transcripts are reduced by therapy correlates with progression-free survival. A consensus meeting at the National Institutes of Health (NIH) in October 2005 made suggestions for (a) harmonizing the different methodologies for measuring BCR-ABL transcripts in patients with CML undergoing treatment and using a conversion factor whereby individual laboratories can express BCR-ABL transcript levels on an internationally agreed scale; (b) using serial Q-PCR results rather than bone marrow cytogenetics or FISH for the BCR-ABL gene to monitor individual patients responding to treatment; and (c) detecting and reporting Ph-positive subpopulations bearing BCR-ABL kinase domain mutations. An international scale for comparison of BCR-ABL mRNA levels has been subsequently developed and implemented to facilitate common interpretation of data derived from individual laboratories and comparison of clinical studies, as well as to guide clinical decision. BCR-ABL values generated by different laboratories were aligned to the international scale such that major molecular response (MMR) was defined as BCR-ABL values of 0.1% or less. Alignment was achieved using laboratory-specific conversion factors calculated by comparisons of results of assays performed with patient samples against a reference method. A validation procedure was completed, and showed that there was good agreement between the overall MMR rates between different validated assays.[3]

In any new patient whose blood count suggests the diagnosis of a chronic myeloproliferative disorder, the detection of BCR-ABL transcripts in a blood specimen is probably the best way to confirm the diagnosis of CML. Current guidelines recommend that circulating BCR-ABL transcript numbers be measured and marrow cytogenetics be studied in every new patient with CML before initiation of treatment. Marrow cytogenetics is essential to identify any unusual translocations or additional cytogenetic abnormalities, and RQ-PCR for BCR-ABL at diagnosis will identify whether the commonly observed e13a2 (b2a2) or e14a2 (b3a2) transcripts are present or whether one of the less common fusion transcripts that are not amplified by the standard primer sets is present. This can prevent confusion if a patient on therapy has undetectable BCR-ABL transcripts because their transcripts were not amplified in the standard assay. If collection of marrow cells is not feasible, FISH performed on a blood specimen using dual probes for the BCR and ABL genes is an alternate method of confirming the diagnosis. FISH may also detect cytogenetically "silent" BCR-ABL rearrangements and deletions in the derivative 9q+, which have prognostic significance, and may therefore be performed in conjunction with marrow cytogenetics and RQ-PCR for BCR-ABL transcripts.

Natural History

The natural history of CML, determined more than 75 years ago, suggests a median survival from diagnosis of approximately 3 years. Without therapy, CML evolves from a chronic phase (CP) to an accelerated phase (AP) and eventually to blast crisis (BC). In approximately 25% of patients, there is no intervening AP between CP and BC (Table 66-1). Median survival times have been significantly prolonged with therapy (discussed later in the Therapy section). Following the introduction of imatinib treatment, a dramatic decrease in CML deaths was seen in age-adjusted death data from the U.S. Surveillance Epidemiology and End Results (SEER) (http://seer.cancer.gov/statistics/).[4] Long-term follow-up of CML patients who achieved complete cytogenetic response (CCR) 2 years after starting imatinib treatment, showed that CML-related deaths are uncommon and survival is not statistically significantly different from that of the general population.[5]

Accelerated Phase

In general, accelerated phase is characterized by symptoms of fever, night sweats, weight loss and bone pain, difficulty in controlling counts using conventional therapy, increased numbers of blasts and early myeloid cells in marrow and peripheral blood, and evidence of karyotypic evolution (Fig. 66-5). The World Health Organization (WHO) classification defines accelerated phase of CML as one or more of the following changes: (a) 10% to 19% myeloblasts in peripheral blood or bone marrow; (b) peripheral blood basophils higher than 20%; (c) persistent thrombocytopenia, less than 100×10^9/L; (d) persistent thrombocytosis, more than 1000×10^9/L unrelated to therapy; (e) increasing WBC count and increasing spleen size unresponsive to therapy; and/or (f) evidence of clonal evolution. The most common cytogenetic changes associated with disease evolution are an additional Ph chromosome, trisomy 8, isochrome I(17q), and trisomy 19.

Blast Crisis

The blast phase of CML resembles acute leukemia. Blast crisis is defined as having more than 20% blasts in the bone marrow or peripheral blood, the presence of large aggregates and clusters of blasts in the bone marrow biopsy, or the development of extramedullary blastic infiltrates. In approximately two-thirds of patients, the blasts have a myeloid or undifferentiated-like phenotype, whereas in the remaining third the blasts appear more lymphoid-like. Immunophenotypic analysis is recommended to characterize the nature of the blasts (Fig. 66-6). Extramedullary blast crisis most commonly affects the skin, lymph nodes, spleen, bone, or central nervous system, but it may occur elsewhere and may be of myeloid or lymphoid lineage.

Table 66-1 WHO Criteria for Accelerated and Blast Phases of CML

Accelerated phase	Diagnosis can be made if one or more of the following is present: Blasts 10% to 19% of peripheral blood white cells or bone marrow cells Peripheral blood basophils at least 20% Persistent thrombocytopenia ($<100 \times 10^9$/L) unrelated to therapy, or persistent thrombocytosis ($>1000 \times 10^9$/L) unresponsive to therapy Increasing spleen size and increasing WBC count unresponsive to therapy Cytogenetic evidence of clonal evolution (i.e., the appearance of an additional genetic abnormality that was not present in the initial specimen at the time of diagnosis of chronic phase CML) Megakaryocytic proliferation in sizable sheets and clusters, associated with marked reticulin or collagen fibrosis, and/or severe granulocytic dysplasia, should be considered as suggestive of CML-AP. (These findings have not yet been analyzed in large clinical studies; thus it is not clear whether they are independent criteria for accelerated phase. They often occur simultaneously with one or more of the other features listed.)
Blast crisis	Diagnosis can be made if one or more of following is present: Blasts 20% or more of peripheral blood white cells or bone marrow cells Extramedullary blast proliferation Large foci or clusters of blasts in bone marrow biopsy

PROGNOSIS

A number of prognostic scoring systems have been developed with the goal of predicting the length of chronic phase in individual patients. The best-known and widely used index was developed by Sokal and colleagues. An algorithm was identified, using spleen size, percentage of circulating blasts, platelet count, and age as prognostic factors for chronic-phase patients. However, the Sokal scale was based on therapies available at that time (busulfan, splenectomy), and newer systems for patients treated with IFN subsequently resulted in newer prognostic scoring systems. These scales, however, may have limited predictive value in the age of tyrosine kinase inhibitors.

Approximately 20% of patients with CML have deletions of chromosomal material of varying size on the derivative 9q+. These deletions presumably occur at the same time as the formation of the Ph chromosome, and are thus not considered to be additional clonal changes as would be suggestive of accelerated-phase disease. Patients with der 9q+ have a worse prognosis if they receive IFN therapy; it is unclear whether or not such deletions have a poor prognosis in patients receiving imatinib therapy.

Population-based studies investigating CML mortality in the imatinib era are now becoming available. They show that the pattern of mortality in CML patients related to high Sokal scores has became similar to those of intermediate scores induced by the use of imatinib in CP-CML patients.[4]

THERAPY

Definitions of Response to Treatment

Hematologic, cytogenetic, and molecular responses to treatment in CML have been defined (Table 66-2). A complete hematologic response is defined as the achievement of normal WBC and platelet counts and normal differential, along with the disappearance of all symptoms and signs of CML. A partial hematologic response is defined as a decrease in the WBC count to less than 50% of the pretreatment level or the normalization of the WBC count accompanied by persistent splenomegaly or immature cells in the peripheral blood. A complete cytogenetic response (CCR) is defined as the absence of Ph-positive metaphases in marrow cells, along with partial cytogenetic response as 1% to 34% Ph-positive metaphases. Major cytogenetic remission combines the percentages of complete and partial response. There is now increasing reliance on BCR-ABL mRNA levels for assessment of response. According to the international scale for comparison of BCR-ABL mRNA levels, a major molecular response (MMR) is defined as a value of 0.1% or less.[3] Lack of detection of BCR-ABL mRNA is referred to as a complete molecular response (CMR). Since the ability to detect BCR-ABL

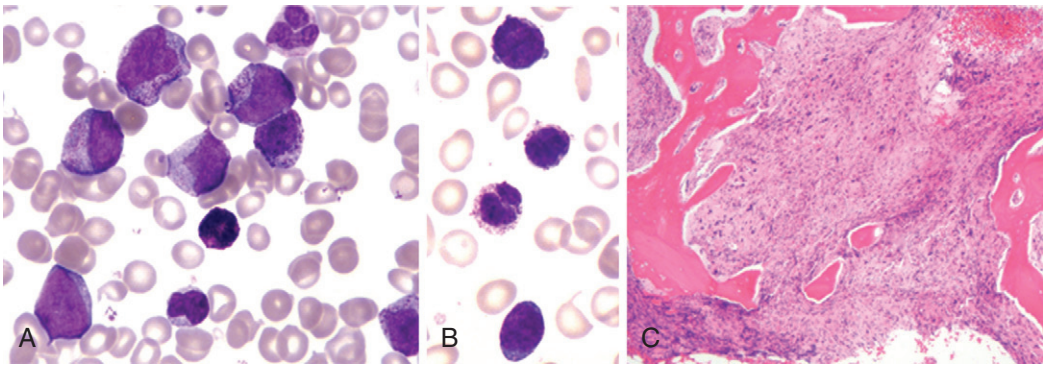

Figure 66-5 CHRONIC MYELOGENOUS LEUKEMIA, ACCELERATED PHASE. **A,** Peripheral smear showing increased immaturity in a case in which blasts were more than 10% of circulating leukocytes. **B,** Peripheral smear illustrating increased basophils, in a case in which basophils were more than 20% of circulating leukocytes. **C,** Bone core biopsy showing increased fibrosis and small dysplastic megakaryocyte. These findings are suggestive of accelerated phase.

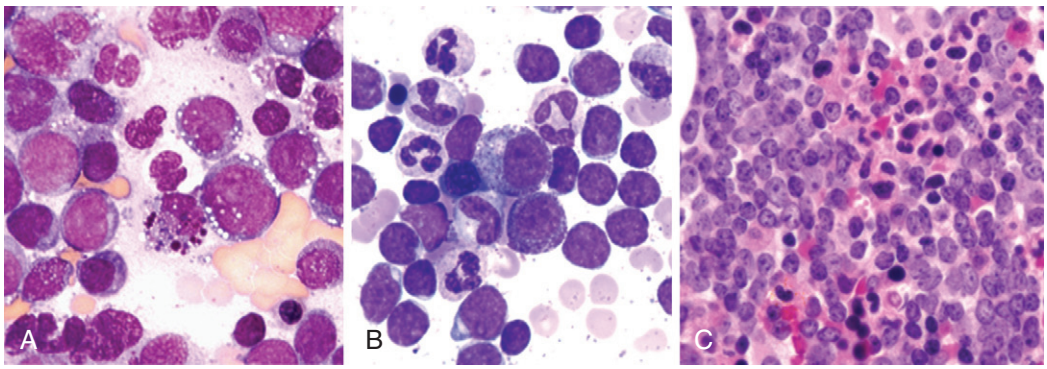

Figure 66-6 CHRONIC MYELOGENOUS LEUKEMIA, BLAST PHASE. **A,** Bone marrow aspirate showing myeloid blast phase associated with t(9;22) and inv(16). Note abnormal eosinophil *(center)*. **B,** Bone marrow aspirate showing lymphoid blast phase in the background of residual CML. **C,** Bone core biopsy illustrating focal blast phase.

Table 66-2 Response Definition and Monitoring

Hematologic Response	Cytogenetic Response	Molecular Response
Complete: Platelet count <450 × 10^9/L; WBC count <10 × 10^9/L; differential without immature granulocytes and with less than 5% basophils; nonpalpable spleen	Complete: Ph+ 0 Major: Ph+ 1%-35% Minor: Ph+ 36%-65 Minimal: Ph+ 66%-95% None: Ph+ <95%	Complete: BCR-ABL transcripts nonquantifiable and nondetectable* Major: ≤0.10%

BCR-ABL to control gene ratio according to the proposed international scale for measuring molecular response, with a standardized "baseline," as established in the IRIS trial, taken to represent 100% on the international scale, and a 3-log reduction from the standardized baseline (MMR) fixed at 0.10%.
*Qualified by the limit of sensitivity of the PCR assay employed.

mRNA depends on the sensitivity of the PCR assay, there is now consensus that CMR be defined based on assay sensitivity (e.g., $CMR^{4.0}$, where BCR-ABL mRNA levels are 0.01% or 4.0 log reduced).

Chemotherapy

Busulfan (BU) chemotherapy for CML was introduced in the 1950s. BU was administered in doses of 4 to 6 mg/day and then held when the WBC count fell to 30 × 10^9/L. The drug effect could persist for weeks, and the counts could fall further after therapy was discontinued. Busulfan therapy was associated with serious adverse effects, including prolonged aplasia, pulmonary fibrosis, and a syndrome simulating adrenal insufficiency.

Treatment with hydroxyurea (HU) was started as an alternative to busulfan. Hydroxyurea therapy is usually initiated at doses of 1 to 6 g/day in an attempt to lower counts. HU administered at doses of 1 to 2 g/day is then used to maintain blood counts in the normal range. Hydroxyurea is less toxic than busulfan. Its major adverse effect is reversible marrow suppression. In randomized trials, hydroxyurea was shown to prolong survival of patients with chronic-phase CML when compared with BU therapy. Median survival of hydroxyurea-treated patients was 5 years compared with 3.75-year median survival of busulfan-treated patients. Because neither drug results in significant selective suppression of the Ph-positive clone, the aim of therapy with these agents is to control disease and symptoms. Hydroxyurea is now commonly used to achieve control of counts simultaneous with, or prior to, initiation of treatment with imatinib or other disease-specific therapies.

Several other chemotherapeutic agents can be used to reduce the white cell counts in CML. Low-dose cytosine arabinoside can be used either as an intermittent bolus or as a daily infusion to control disease in cases where neither HU nor BU is proving useful. Cytosine arabinoside has also been used in combination with other agents, including IFN and imatinib in an attempt to enhance response.

Hyperuricemia and hyperuricosuria are frequently encountered problems in newly diagnosed and relapsed CML patients. Allopurinol, given at a dose of 300 mg daily and adequate hydration should be started before initiating treatment. Allopurinol should be discontinued after the WBC count has been controlled.

Interferon

Pioneering observational studies initiated in the 1980s by investigators at the MD Anderson Cancer Center provided evidence for efficacy of IFN in CML and indicated a 70% to 80% probability of complete hematologic remission in selected CML patients. Initial research involved the use of human leukocyte IFN, but subsequent clinical studies used recombinant human interferon-α (rIFN-α). Recombinant interferon-γ (rIFN-γ) has been shown to be relatively ineffective for CML. The potential mechanisms by which IFN works in CML are not understood but may include inhibition of increased proliferation, correction of the adhesion defect of the malignant progenitor in CML, or stimulating an immune response to CML. Rates for complete and partial cytogenetic remissions range from 0% to 38%. Evidence exists for a dose-response relationship, with IFN doses of 4 to 5 million units/m^2/day more likely to achieve remission (and toxicity) than lower doses. Durable remissions are more common in young patients, those treated soon after diagnosis, patients with less advanced stage disease, and those with favorable prognostic outlook. Hematologic remissions usually occur within 1 to 3 months after starting IFN. The median time to complete cytogenetic response is 9 to 18 months but may occur after 4 years of therapy. Durable cytogenetic responses, some lasting as long as 10 years, are more common in patients who achieve a complete cytogenetic response compared with partial cytogenetic remission.

Virtually all patients receiving IFN experience constitutional adverse effects, and discontinuation of treatment as a result of toxicity is necessary for 4% to 18% of patients compared with 1% of those receiving hydroxyurea. Acute adverse effects are generally mild to

moderate and include flu-like symptoms such as fever, chills, and malaise. A constellation of other more severe acute reactions and chronic complications can occur. Overall, the mechanisms underlying the toxic effects are not well understood, but adverse effects 'are usually dose- and duration-dependent.

Randomized studies show an improvement in survival rates in patients receiving IFN compared with patients receiving busulfan or hydroxyurea. An Italian multicenter study randomly assigned 218 patients to receive IFN and 104 patients to receive HU or BU (the control group). Cytogenetic remissions were significantly more common in the IFN group. After a median follow-up of 68 months, the observed 6-year survival rate was 50% for IFN-treated patients and 29% for controls, with median survivals of 72 and 52 months, respectively. The time for progression from chronic phase to accelerated or blast phase was lengthened from 45 months to more than 72 months. In a German multicenter study, 622 patients were randomized to receive IFN, BU, or HU. The 5-year survival rate in the IFN group (59%) exceeded that of the BU group (32%) but was not significantly higher than that of the HU group (44%). Much of the discrepancy between the Italian and German findings can be explained by differences in case mix and treatment regimens. Two other randomized trials also showed benefit for IFN treatment compared with chemotherapy. The UK Medical Research Council randomly assigned 293 patients to receive IFN and 294 patients to receive HU or BU. The 5-year survival rate was 52% for the IFN group and 34% for the control group. A Japanese randomized control trial compared IFN (80 patients) with BU (79 patients). Hematologic and cytogenetic remission rates did not differ significantly. After a median follow-up of 50 months, the predicted 5-year survival rate was 54% for patients receiving IFN and 32% for those receiving BU.

The added value of combining IFN with cytosine arabinoside was shown in a French multicenter trial, wherein 360 patients were randomly assigned to receive IFN combined with cytosine arabinoside (20 mg/m^2/day for 10 days) and 361 patients to receive only IFN. After 3 years, the survival rate was 86% with IFN and cytosine arabinoside and 79% with IFN alone. The rate of hematologic response was higher in the IFN–cytosine arabinoside group than in the IFN group. Major cytogenetic responses were observed 12 months after randomization in 41% of patients treated with IFN-cytosine arabinoside and in 24% of patients treated with IFN only.

Thus accumulated evidence from randomized trials suggests that IFN improves survival in chronic-phase patients with favorable features compared with BU and HU. Metaanalysis suggests that the pooled 5-year survival rate is 57% (50%-59%) for IFN and 42% (29%-44%) for chemotherapy, which results from a delay in the onset of blast crisis. The controlled trials suggest that IFN increases life expectancy by a median of approximately 20 months compared with BU and HU. There is no direct evidence that IFN has a greater impact on survival than does HU for patients who are in the later stages of chronic phase (e.g., more than 1 year after diagnosis) or for those who are more ill (e.g., more than 10% to 30% blasts in peripheral blood). Adding cytosine arabinoside to IFN appears to add further survival benefit but also increases toxicity. Although IFN clearly is beneficial in patients with CML patients, benefit is limited by low levels of cytogenetic response and considerable toxicity. As discussed later, the use of IFN in the modern treatment of CML patients has been replaced by use of imatinib and other tyrosine kinase inhibitors.

Tyrosine Kinase Inhibitor Treatment

Because the tyrosine kinase activity of BCR-ABL plays a critical role in cellular transformation, it is an attractive target for inhibition. The introduction of TKIs into clinical practice has dramatically changed CML treatment. Tyrosine kinase inhibitor therapy, now the mainstay of treatment, is remarkably effective for chronic-phase CML, inducing remissions in most patients and leading to excellent survival. Tyrosine kinase inhibitor resistance can occur, especially in accelerated phase and blast crisis CML, usually as a result of tyrosine kinase domain point mutations. Resistance to imatinib can often be treated by "second generation" TKIs, dasatinib, or nilotinib, and there is evidence that these drugs may be even more effective than imatinib for front-line treatment of CML. Molecular endpoints that correlate with long-term outcomes have been developed and have been incorporated into guidelines to monitor response to tyrosine kinase inhibitors treatment (see box on Can Tyrosine Kinase Inhibitor Treatment Cure Chronic Myeloid Leukemia?).

Imatinib Mesylate

Imatinib mesylate is a small, 2-phenylaminopyrimidine molecule that inhibits the kinase activity of all proteins that contain ABL,

Can Tyrosine Kinase Inhibitor Treatment Cure Chronic Myeloid Leukemia?

An increasing proportion of CML patients treated with tyrosine kinase inhibitors may not have detectable levels of the BCR-ABL gene, even with sensitive PCR assays. This raises the question as to whether patients can actually be cured with tyrosine inhibitor treatment. Patients with negative PCR may still have significant numbers of residual malignant cells. The definition of a *cure* remains controversial. Although *cure* might theoretically require the total eradication of all leukemia cells, it can be argued that patients may be considered cured if low numbers of leukemia cells still persist but are not expected to be able to reestablish clinical disease. Such a situation may occur in CML after allogeneic transplantation in which a graft-versus-leukemia effect may help maintain remission. In AML associated with the t(8;21), many long-term survivors continue to demonstrate molecular evidence of this translocation. On the other hand, late relapses can be observed in patients with childhood ALL more than 10 years after remission, with molecular evidence that the relapse originated from the same clone that caused the disease originally.

Therefore it is important to consider whether BCR-ABL–expressing cells that escape elimination with imatinib include cells with leukemogenic potential. Mathematical modeling of the effect of imatinib on different hematopoietic cell compartments in CML suggests that leukemia stem cells are resistant to elimination by this drug. This is supported by evidence that BCR-ABL–positive stem and progenitor cells are retained in patients in CCR on imatinib treatment, including patients with sustained undetectable molecular evidence of disease by RT-PCR. In vitro treatment with tyrosine kinase inhibitors inhibits proliferation of CML primitive progenitors but only modestly increases apoptosis. Similarly, tyrosine kinase inhibitor treatment fails to eradicate primitive leukemia cells in a mouse model of CML. These observations suggest that TKI treatment does not eliminate primitive leukemogenic cells. On the other hand, some patients can maintain a BCR-ABL–negative status for more than 1 year following discontinuation of imatinib treatment. Although the long-term durability and frequency of such responses are not clear at present, these observations suggest that additional factors related to the frequency and leukemogenic potential of residual cells, or immune or microenvironmental factors determine the risk for relapse after discontinuation of tyrosine kinase inhibitor treatment.

In the future, a better understanding of these factors will allow for improved prediction of patients in whom treatment can be safely stopped. In addition, better understanding of the mechanisms underlying persistence of leukemogenic cells may allow development of improved strategies to enhance the number of CML patients in whom TKI treatment can be stopped and who are considered effectively "cured."

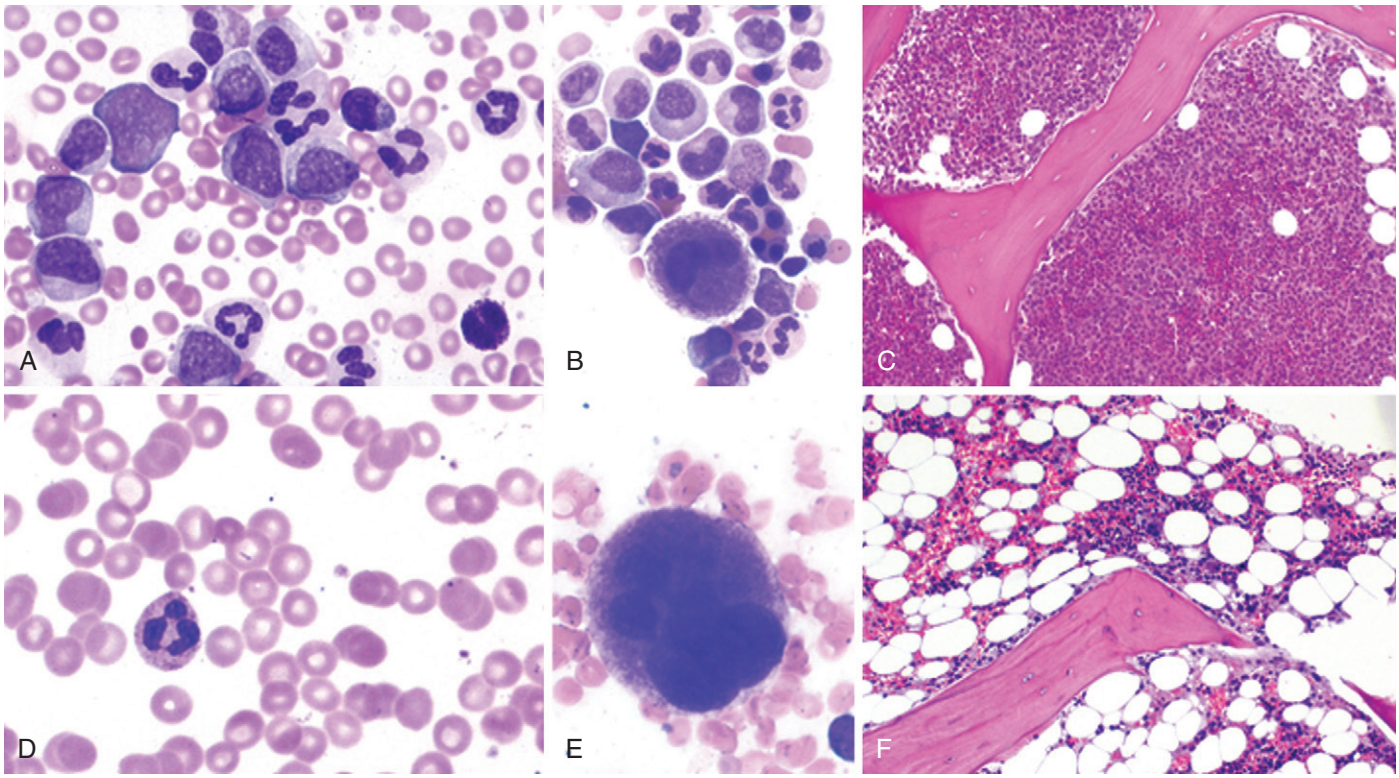
ABL-related gene (ARG) protein, or platelet-derived growth factor receptor, as well as the KIT receptor, at micromole concentrations.[6] Imatinib is a competitive inhibitor that acts at the ATP-binding site in the kinase domain to inhibit the normal binding of ATP and blocks the ability of BCR-ABL to phosphorylate tyrosine residues on its substrates (Fig. 66-7).

Initial phase 1 and phase 2 trials established that imatinib was well tolerated and induced hematologic as well as cytogenetic response in the majority of patients with chronic-phase CML in whom other treatments had failed.[7] In a phase II study, 532 chronic-phase patients who were refractory to or intolerant of IFN-α were treated with imatinib at a dose of 400 mg daily. A CHR was achieved in 95% of patients, major cytogenetic remission (MCR) in 60% of patients, and CCR in 41% of patients. With a median follow-up of 18 months, the estimated progression-free survival was 89%. Only 2% of patients discontinued therapy because of adverse events.

Subsequently the International Randomized Interferon and STI571 (IRIS) study compared imatinib at 400 mg daily with IFN-α plus cytosine arabinoside in 1106 newly diagnosed patients in first chronic phase. This study was closed with the conclusion that imatinib is the initial nontransplant treatment of choice for patients with newly diagnosed chronic-phase CML. This conclusion was based primarily on a higher rate of disease progression in the patient group receiving IFN plus cytosine arabinoside. In the initial report from this study, after a median follow-up of 19 months, the estimated rate of an MCR at 18 months was 87.1% (95% CI, 84.1-90.0) in the imatinib group and 34.7% (95% CI, 29.3-40.0) in the IFN plus cytosine arabinoside group (P <0.001).[8] The estimated rates of CCR were 76.2% (95% CI, 72.5-79.9) and 14.5% (95% CI, 10.5-18.5), respectively (P <0.001). At 18 months, the estimated rate of freedom from progression to accelerated-phase or blast-crisis CML was 96.7% in the imatinib group and 91.5% in the IFN group (P <0.001). Imatinib was better tolerated than combination therapy. In a subsequent 60-month follow-up report for this study, the estimated cumulative incidence rate of CHR, MCR, and CCR for patients on first-line imatinib was 98%, 92%, and 87% at 60 months (Fig. 66-8). Only 7% of patients progressed to advanced phase, and the estimated overall survival was 89%. Crossover between arms was permitted for treatment failure, and 382 (69%) of 553 patients originally allocated to the IFN/cytarabine arm crossed over to the imatinib arm at a median of 60 months from start of treatment. The main reason for crossover from IFN to imatinib was intolerance of treatment, but reasons also included disease progression and failure to achieve hematologic or cytogenetic response. During the sixth year of study treatment, there were no further reports of disease progression and the toxicity profile remained unchanged. Of all patients randomized to receive imatinib and still on study treatment, 63% showed CCR at last assessment. The estimated event-free survival at 6 years was 83%, and the estimated overall survival was 88%.[9]

A dose of 400 mg of imatinib daily is currently the standard dose for initiating therapy in newly diagnosed chronic-phase patients. Nonrandomized studies suggested that patients receiving initial therapy with 800 mg imatinib daily will achieve CCR more rapidly than patients receiving standard 400-mg daily doses. The Tyrosine Kinase Inhibitor Optimization and Selectivity (TOPS) study compared imatinib 800 mg/day (n = 319) to 400 mg/day (n = 157). Higher-dose imatinib provided faster response CCR rates at 6 months (57% versus 45%, respectively), but there was no significant difference between the arms at 12 months (70% versus 66%, respectively) or 24 months (76% in both groups). Similarly, no difference in EFS, progression-free survival (PFS), or overall survival was seen. However, a subset of patients who can tolerate higher doses of imatinib, without interruptions for side effects, can have a better response.[10]

Cumulative response estimates do not take into account patients who have left the study for a variety of reasons. It is also clear that the results of imatinib therapy in the community setting are less favorable. Thus only 55% of patients treated with first-line



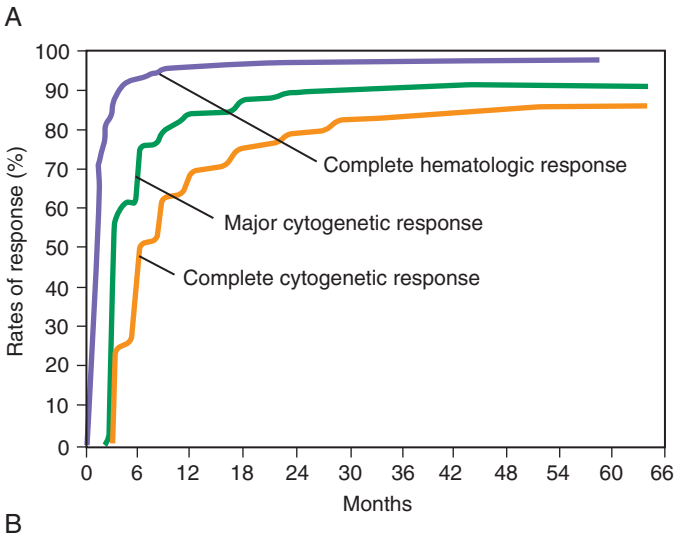


Figure 66-7 CHRONIC MYELOGENOUS LEUKEMIA, BEFORE AND 3 MONTHS AFTER IMATINIB THERAPY. imatinib in the IRIS study were still receiving imatinib at follow-up of 8 years, while the remainder had discontinued therapy as a result of inadequate therapeutic effect or toxicity. A report from the Hammersmith Hospital, which defined imatinib failure more broadly than the IRIS study as discontinuation of drug for any reason, including toxicity as well as a lack of major cytogenetic response, calculated 5 years EFS at only 63%.[11]

Comparison of health-related quality of life (QOL) of imatinib-treated patients and the general population indicated marked impairments of QOL in younger patients, especially between 18 and 39 years, related to physical and emotional problems. Women had worse QOL than men. The most frequently reported symptom was fatigue. Patients older than 60 years had QOL similar to that of the general population.[12]

Prognostic Indicators

Pretreatment risk factors can predict the likelihood of achieving and maintaining response to imatinib. At 60 months, the estimated risk for disease progression was significantly higher for patients with a higher pretreatment Sokal score (estimated rates for high-risk, intermediate-risk, and low-risk groups of 17%, 8%, and 3%, respectively; $P<0.002$).

The achievement of certain milestones of response can also predict prognosis. For example, patients who do not experience a complete hematologic response by 3 months of treatment, any cytogenetic response by 6 months, or a major cytogenetic response by 12 months do poorly in comparison with patients achieving these milestones. Reduction of BCR-ABL levels observed with cytogenetic and quantitative PCR monitoring is also predictive of prognosis (Fig. 66-9). A landmark analysis indicated that at 60 months, 97% of the patients (95% CI, 94 to 99) who had achieved CCR at 12 months after the initiation of imatinib treatment (n = 350) had not progressed to accelerated phase or blast crisis (see Fig. 66-9). For patients who did not have an MCR within 12 months (n = 73), the estimate was 81% (95% CI, 70-92; P <0.001). Of interest, the Sokal score was not

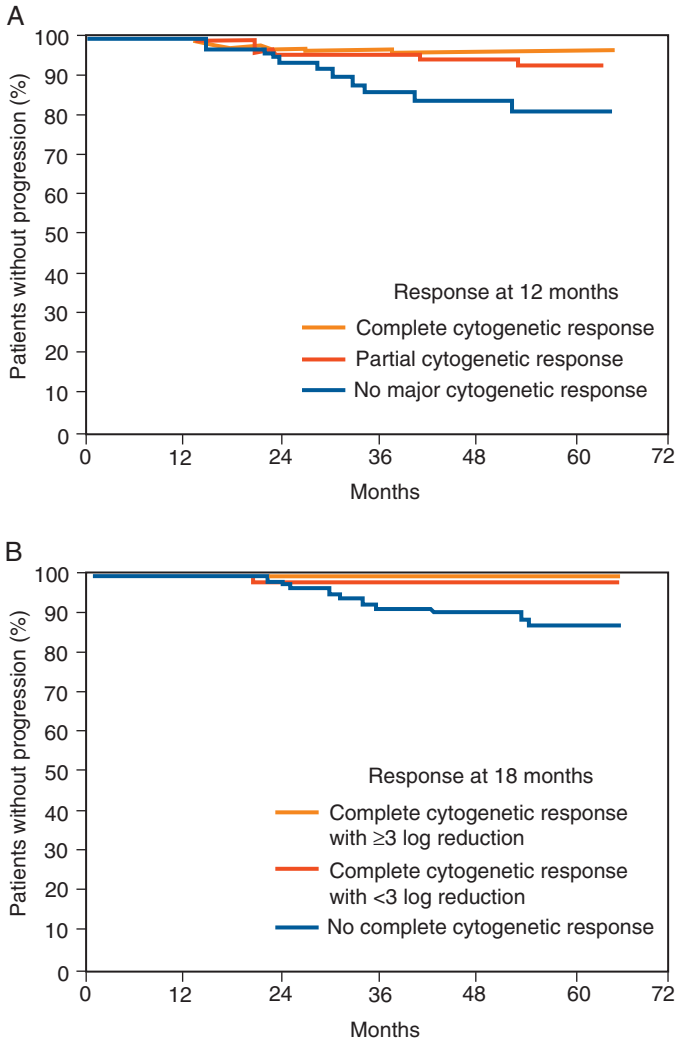

Figure 66-9 EVENT FREE SURVIVAL (EFS) OF NEWLY DIAGNOSED CHRONIC MYELOID LEUKEMIA (CML) PATIENTS TREATED WITH IMATINIB MESYLATE AFTER 7 YEARS' FOLLOW-UP ON THE INTERNATIONAL RANDOMIZED INTERFERON AND STI571 (IRIS) STUDY BASED ON MOLECULAR RESPONSE AT 6- **(A),** 12- **(B),** AND 18-MONTH **(C)** LANDMARKS. *(Data from Hughes TP, Hochhaus A, Branford S, et al: Long-term prognostic significance of early molecular response to imatinib in newly diagnosed chronic myeloid leukemia: An analysis from the International Randomized Study of Interferon and STI571 (IRIS),* Blood *116:3758, 2010.)*

predictive of risk for disease progression in patients who had a complete cytogenetic response (95%, 95%, and 99% in the high-risk, intermediate-risk, and low-risk groups, respectively; $P = 0.20$). The prognostic significance of molecular responses at 6-, 12-, and 18-month in predicting event-free survival (EFS) and time to progression to accelerated phase/blast crisis at 7 years was evaluated in the IRIS cohort. Patients with BCR-ABL mRNA levels >10% at 6 months and >1% at 12 months using the international scale had inferior EFS and higher rate of progression compared with all other molecular response groups. Conversely, patients who achieved major molecular response (BCR-ABL [IS] <0.1%) by 18 months enjoyed durable responses, with no progression, 95% EFS, and only 3% probability of loss of CCyR at 7 years.[13] An analysis from the Hammersmith group, patients with BCR-ABL mRNA levels >9.84% at 3 months had significantly lower 8-year probabilities of OS (56.9% versus 93.3%; P <0.001), progression-free survival, cumulative incidence of CCyR, and complete molecular response than those with higher levels. Similarly, BCR-ABL mRNA levels >1.67% at 6 months and >0.53% at 12 months also identified patients at increased risk for progression.[14] These results indicate a strong association between the degree of reduction of BCR-ABL transcript numbers and long-term clinical outcome and have led to the adoption of time-dependent molecular response measurements in determining optimal response to therapy (Table 66-3).[15]

Lack of adherence to medication is a major underlying reason for failure of treatment. It has been reported, on multivariate analysis, that in CML patients treated with imatinib for some years, the adherence rate and failure to achieve a major molecular response were the only independent predictors for loss of CCR and discontinuation of imatinib, and poor adherence may be the predominant reason for inability to obtain adequate molecular responses.[16,17]

Results of Treatment in Accelerated Phase and Blast Crisis

A phase II study in accelerated-phase patients enrolled 235 patients. Some hematologic response was seen in 82% of patients, with 34% of patients achieving a CHR. A major cytogenetic response occurred in 24% of patients, with 17% complete responses. Estimated 12-month progression-free and overall survival rates were 59% and 74%, respectively.

A phase II study of 260 patients in myeloid blast crisis who were treated with imatinib showed an overall response rate of 52%, with sustained hematologic responses lasting at least 4 weeks in 31% of patients. Eight percent of patients achieved a complete remission with peripheral blood recovery. Another 4% of patients cleared their marrows to less than 5% blasts but did not meet the criteria for CR because of persistent cytopenias. Eighteen percent of patients either "returned" to chronic phase or had partial responses. Major cytogenetic responses were seen in 16% of patients, with 7% having complete cytogenetic responses. The median survival was 7 months. These results compare favorably with historical controls treated with chemotherapy for myeloid blast crisis in which the median survival is approximately 3 months. In patients with Ph-positive ALL, 29/48 (60%) responded to a single agent, imatinib. However, the duration of response was relatively short, with a median estimated time to disease progression of only 2 months.

Toxicity

Myelosuppression is particularly common in CML patients treated with imatinib and is more common in patients with advanced disease. In the phase III randomized trial of newly diagnosed patients in the chronic phase, grade 3 neutropenia (ANC <1000/mm^3) was experienced by 11% of patients, grade 4 neutropenia (ANC <500/mm^3) occurred in 2% of patients, grade 3 thrombocytopenia (platelets <50,000/mm^3) occurred in 6.9% of patients, and grade 4 thrombocytopenia (platelets <10,000/mm^3) occurred in less than 1% of patients. Myelosuppression can occur at any time during imatinib therapy, but it usually begins within the first 2 to 4 weeks of starting therapy for blast crisis, with a slightly later onset in patients in accelerated or chronic phase. Although grade 3 and 4 neutropenia is frequent, particularly in advanced phases, infectious complications are relatively rare, possibly related to the lack of mucous membrane

Table 66-3 Evaluation of Overall Response to Imatinib First-Line in Early Chronic Phase

	Response			
Evaluation Time (Months)	**Optimal**	**Suboptimal**	**Failure**	**Warnings**
Baseline	NA	NA	NA	High risk; CCA/Ph+*
3	CHR and at least minor CyR (Ph+ ≤65%)	No CyR (Ph+ >95%)	Less than CHR	NA
6	At least PCyR (Ph+ ≤35%)	Less than PCyR (Ph+ >35%)	No CyR (Ph+ >95%)	NA
12	CCR	PCyR (Ph+ 1%-35%)	Less than PCyR (Ph+ >35%)	Less than MMR†
18	MMR†	Less than MMR†	Less than CCR	NA
Any time during treatment	Stable or improving MMR†	Loss of MMR†; mutations‡	Loss of CHR; loss of CCR; mutations§; CCA/Ph+	Increase in transcript levels‖; CCA/Ph+

From Baccarani M, Cortes J, Pane F, et al: Chronic myeloid leukemia: An update of concepts and management recommendations of European LeukemiaNet, *J Clin Oncol* 27:6041, 2009.
CCA, clonal chromosome abnormalities; *CCR,* complete cytogenetic response; *CHR,* complete hematologic response; *CyR,* cytogenetic response; *MMR,* major molecular response; *NA,* Not applicable; *PCyR,* partial cytogenetic response; *Ph+,* Philadelphia chromosome positive.
*CCA/Ph+ is a warning factor at diagnosis, although its occurrence during treatment (i.e., clonal progression) is a marker of treatment failure. Two consecutive cytogenetic tests are required and must show the same CCA in at least two Ph+ cells.
†MMR indicates a ratio of BCR-ABL1 to ABL1 or other housekeeping genes of ≤0.1% on the international scale.
‡BCR-ABL1 kinase domain mutations still sensitive to imatinib.
§BCR-ABL1 kinase domain mutations poorly sensitive to imatinib.
‖The significance of the increase may vary by a factor of 2 to 10, depending on the laboratories.
Treatment recommendations:
- Optimal: Continue imatinib 400 mg/day.
- Suboptimal: Continue imatinib same dose; or test high-dose imatinib, dasatinib, or nilotinib.
- Failure: Dasatinib or nilotinib; third-generation agents or alloHSCT in patients who carry the T315I mutation; alloHSCT in patients who have experienced progression to AP/BP.

damage in patients on imatinib. Central nervous system and gastrointestinal hemorrhages may occur, most frequently in patients in blast crisis with platelet counts less than 20,000 and with uncontrolled leukemia. The primary goal in treating otherwise healthy patients in chronic phase is to avoid the risk for potentially dangerous neutropenia and platelet transfusion dependence. For patients with blast crisis or high-risk accelerated-phase disease (>15% blasts), a suggested approach is to balance risks and benefits, and support patients with a platelet count under 10,000/mm^3 or under 50,000/mm^3 with clinically evident bleeding with platelet transfusions. In the event of clinically significant bleeding, imatinib should be held immediately, until the bleeding is controlled. In patients whose absolute neutrophil count is less than 500/mm^3, imatinib should be continued if the marrow is hypercellular or if there are >30% blasts. In cases where the marrow is hypocellular and the ANC is <500/mm^3 for 2 to 4 weeks, imatinib may be held, the dose may be reduced, or myeloid growth factors can be used. Concurrent administration of growth factors and imatinib is well tolerated, and patients have not experienced a greater rate of relapse.[18]

The most common nonhematologic adverse events related to imatinib were nausea, muscle cramps, fluid retention, diarrhea, musculoskeletal pain, fatigue, and skin rashes. Only a minority of patients experienced grade 3 or 4 toxicity, and there was a low rate of discontinuance of therapy because of toxicity of 5%, 3%, and 2% in the phase II studies for blast crisis, accelerated phase, and chronic phase, respectively. The higher rate of severe toxicity in patients with advanced-phase disease may relate to the higher doses administered or to the poorer underlying health of patients. Most adverse effects can be managed successfully with supportive measures. Some toxicities (e.g., mild skin rashes, mild elevations of transaminases, bone pain, and arthralgias) may improve spontaneously despite continued therapy at the same dosage.

Imatinib Resistance

Both de novo and acquired resistance have been observed in imatinib-treated CML patients. The most commonly described mechanisms associated with resistance are point mutations in the BCR-ABL gene that prevent imatinib from inhibiting kinase activity and BCR-ABL gene amplification. BCR-ABL-independent mechanisms may also play a role in imatinib resistance in some patients. Activation of the SRC family kinases, LYN, has been demonstrated in cells from patients with acquired imatinib resistance. The Sawyers group, in an original study of nine patients who relapsed on imatinib treatment, detected BCR-ABL gene amplification in three patients and kinase domain mutations in six. Relapse was associated with reactivation of BCR-ABL kinase activity. Subsequent studies have shown that there are >90 different amino acid substitutions detected in imatinib-resistant patients ones (see Fig. 66-1), occurring with varying frequency.[19] The different mutations conferred varying degrees of imatinib resistance. In patients with stable chronic-phase disease, detection of mutations correlated with subsequent disease progression. Mutations have been found in some patients before the start of treatment, supporting a model in which preexisting BCR-ABL mutations that confer imatinib resistance acquire a selective clonal growth advantage during imatinib treatment.

Intensive efforts have been made to characterize the biologic and clinical significance of BCR-ABL kinase mutations and to develop kinase inhibitors with efficacy against the maximum number of mutants. The structure of the ABL kinase domain in complex with imatinib has been solved. This information sheds light on the mechanisms by which kinase domain mutations confer drug resistance. Mutations may affect residues that directly contact imatinib, such as a mutation resulting in substitution of isoleucine for threonine in the T315 position (T315I). Mutations in the P-loop of the ABL kinase prevent conformational changes required for imatinib binding. Imatinib captures and stabilizes the ABL kinase in its inactive conformation, but is sterically excluded from the active conformation. The M351T mutation and mutations in the activation loop result in the kinase remaining in the active conformation rather than the inactive conformation required for imatinib binding. Clinical experience with the second-generation TKIs dasatinib and nilotinib demonstrates that a much narrower spectrum of mutations retain insensitivity to these agents. These mutations are nonoverlapping, with the exception of the T315I mutation.

Knowledge of BCR-ABL mutation status is being integrated into therapeutic decision-making algorithms for patients. The European Leukemia Net guidelines for the use of mutation testing in management of CML patients recommends mutation testing in chronic-phase CML patients receiving first-line imatinib treatment only in case of failure or suboptimal response. Mutation analysis is recommended in imatinib-resistant patients receiving an alternative TKI in case of hematologic or cytogenetic failure.[19]

Second-Generation Tyrosine Kinase Inhibitors

Because the active conformations of ABL and SRC bear a high degree of structural similarity, compounds with SRC kinase inhibitory activity have been evaluated against native and mutant BCR-ABL. BMS-354825 (dasatinib, Sprycel) is a dual SRC-ABL kinase inhibitor that exhibits approximately 300-fold higher potency against native BCR-ABL. Dasatinib can effectively inhibit most clinically detected BCR-ABL kinase domain mutants at low nanomolar concentrations, with the notable exception of T315I. Another compound, AMN107 (nilotinib) was generated by rational modification of imatinib to enhance BCR-ABL kinase binding activity. Nilotinib binds ABL but with significantly increased avidity and can overcome resistance of most kinase domain mutants, with the exception of T315I. It is evident, however, that both agents have significant activity in imatinib-resistant CML. Of note, responses occurred in patients with and without BCR-ABL kinase domain mutations at trial entry, with the exception of patients with the T315I mutation. Responses in chronic phase and, to a lesser extent, in accelerated phase have been stable. In contrast, many patients with myeloid, and all patients with lymphoid, blast crisis, or Ph-positive ALL have relapsed. These data are similar to the results of the initial studies with imatinib and indicate that once the disease has progressed beyond the chronic phase, tyrosine kinase inhibitor-based monotherapy is not sufficient to induce lasting responses. Both dasatinib and nilotinib are approved for the treatment of patients with CML that is resistant to imatinib and those who are intolerant to the drug. Both agents are quite effective in resistant disease, yielding CCR in approximately 50% of chronic phase cases (for cases who discontinue imatinib because of drug intolerance, the CCR rates are >70%).

Because of this strong clinical activity, both drugs have been tried as first-line therapy in newly diagnosed chronic-phase CML. Two single-center trials of dasatinib and nilotinib have been performed at M.D. Anderson. At 18 to 24 months, both agents showed a similarly small, but consistent benefit in CCR over historical controls treated on imatinib trials. An Italian phase II study of nilotinib in newly diagnosed chronic phase cases showed a similarly high rate of CCR of >90% after 12 months of therapy. Dasatinib and nilotinib were compared with imatinib for frontline treatment of chronic phase CML. The Dasatinib Versus Imatinib Study in Treatment-Naïve CML (DASISION) study tested 100 mg dasatinib daily versus 400 mg imatinib daily.[20] The Evaluating Nilotinib Efficacy and Safety in Clinical Trials Newly Diagnosed Patients (ENESTnd) study compared two nilotinib doses (400 mg twice daily and 300 mg twice daily) with imatinib 400 mg daily.[21] Both studies found the experimental arms (dasatinib and nilotinib) to be superior to imatinib in achieving the primary endpoints (dasatinib: CCR by 12 months; nilotinib: MMR at 12 months). Patients treated with nilotinib had a significantly reduced risk for progression. Based on these results, both nilotinib and dasatinib were approved for frontline therapy of newly diagnosed chronic-phase CML patients in the United States in 2010.

The choice of TKI in newly diagnosed patients remains open to debate. Dasatinib and nilotinib are associated with faster and deeper reduction in leukemia burden. On the other hand, no differences in

OS have been observed yet, although follow-up is required and long-term data from the randomized clinical studies are needed to confirm the initial findings. Imatinib is less expensive, and there is longer experience with its use. A direct comparison between nilotinib and dasatinib has not been performed. Since their overall efficacy appears to be similar, the selection may be based primarily on side effect profile and convenience. Dasatinib treatment is associated with higher rates of myelosuppression and with pericardial and pleural effusion. In contrast, nilotinib can induce an increase in pancreatic enzymes, although radiographic/clinical pancreatitis is rarely noted. Hyperglycemia and hyperbilirubinemia are observed in some nilotinib-treated patients. Skin rash also is a prominent side effect of nilotinib therapy, but this is usually moderate and/or resolves spontaneously. Severe, uncontrolled diabetes and past pancreatitis may be considered as risk factors for nilotinib use, whereas patients with a history of hypertension, asthma, pneumonia, gastrointestinal bleeding, chronic obstructive pulmonary disease, congestive heart failure, autoimmune disorders, or concomitant aspirin use may be at increased risk for pleural and pericardial effusions, bleeding, and infection with dasatinib.

Drugs Targeting the T315I Mutation

The fact that the T315I mutant is not responsive to either dasatinib or nilotinib and that this mutant has been detected in some patients with acquired resistance to dasatinib and nilotinib underscores the need for drugs with T315I inhibitory activity.[22] Ponatinib is a multi-targeted kinase inhibitor active against all BCR-ABL mutants, including T315I. In a phase I study, more than 50% of patients in chronic phase, mostly patients in whom two or more TKIs had failed, attained CCR.[22,23] The CCR rate approached 100% in patients with the T315I mutation. Responses were less frequent and less stable in patients with advanced disease. The BCR-ABL switch pocket inhibitor DCC-2036 binds to an allosteric site in the enzyme and is also active against a broad spectrum of kinase domain mutants, including T315I.[24] This agent is undergoing clinical evaluation.

Residual Disease in Patients Treated With Tyrosine Kinase Inhibitors

Currently, the reverse-transcriptase polymerase chain reaction (RT-PCR) is the most sensitive method for detecting low numbers of BCR-ABL transcripts in a patient after apparently successful hematopoietic cell transplantation. Most patients who have been treated with imatinib and have responded well continue to demonstrate evidence of residual disease using sensitive PCR assays. Recent updates of clinical trials of imatinib in CP CML patients indicate that an increasing proportion of patients appear to enter a molecular remission over time, including some patients achieving a PCR-undetectable status. However, even patients with negative PCR (so-called complete molecular response) may still have significant numbers of residual malignant cells. Several groups have identified BCR-ABL–expressing leukemia stem cells in patients with sustained undetectable molecular residual remission. The French STIM (*S*top *IM*atinib) trial evaluated outcomes after imatinib discontinuation in patients with sustained undetectable MRD for more than 2 years. Approximately 40% of patients did not develop molecular recurrence after 1 year.[25] However, molecular relapse occurred in a substantial proportion of even this highly selected population. Patients with undetectable MRD after imatinib therapy continued to have BCR-ABL rearrangement detectable at the genomic level, indicating persistence of residual leukemic cells not detected by RT-PCR. It is important to note that residual leukemic cells with leukemia-initiating capacity have been shown to persist in CML patients in sustained molecular remission on imatinib.[26] Together, these data suggest that imatinib alone may not be capable of eradicating the leukemic cell clone, and at present, patients are recommended to continue medication indefinitely.

Allogeneic Hematopoietic Cell Transplantation

The Seattle team reported initial results of HLA-matched sibling donor hematopoietic cell transplants performed as therapy for 10 CML patients in 1982, and subsequently published a larger study on 167 patients transplanted from matched siblings through 1983. Long-term follow-up demonstrates that approximately 40% of patients transplanted in chronic phase nearly 20 years ago are surviving. Hematopoietic cell transplant became the first curative treatment in CML. Data from 4267 recipients of matched-sibling transplants reported to the IBMTR between 1994 and 1999 show a probability of survival of 69% ± 2% for 2876 patients transplanted within the first year from diagnosis, and 57% ± 3% for 1391 patients transplanted more than 1 year from diagnosis. Contemporary results from selected single institutions continue to demonstrate excellent outcomes with HCT, in part because of advances in preparative regimens, supportive care, and HLA typing for unrelated donors (Fig. 66-10). For example, the Seattle group has recently reported on their most recent trial using a preparative regimen of targeted busulfan plus cyclophosphamide (CY) in 131 consecutive chronic-phase CML patients. Survival 3 years posttransplant was 86%, and 87% of surviving patients were molecularly negative for BCR-ABL.

The outcome of allogeneic HCT in CML is influenced by many factors, the most important of which is the phase of disease. Other

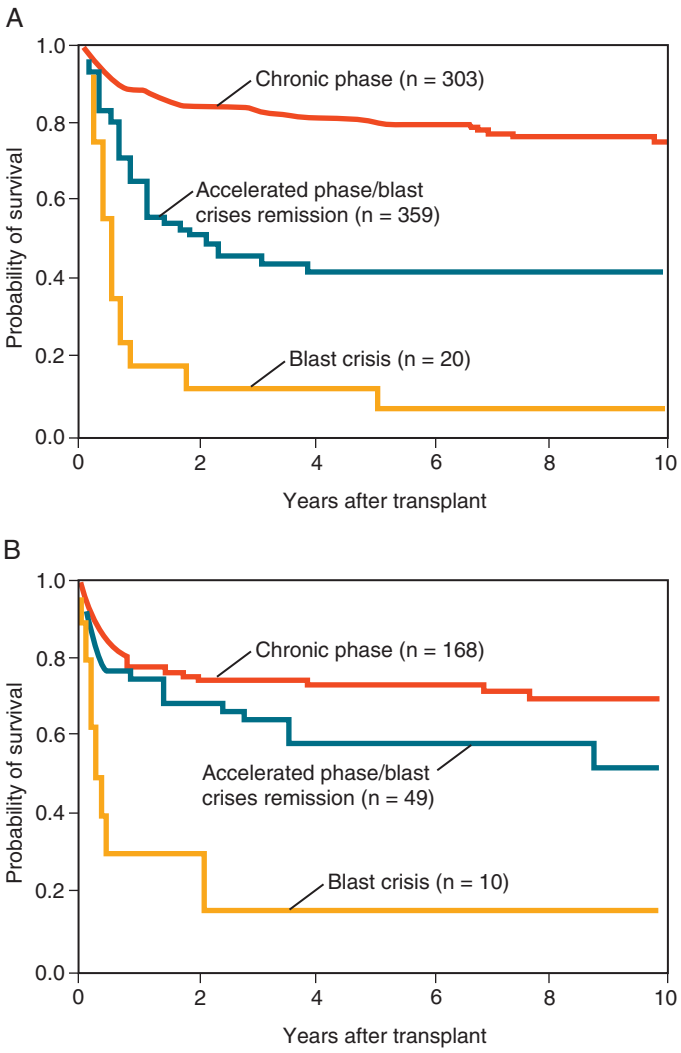

Figure 66-10 Probability of survival following **(A)** related donor transplantation and **(B)** unrelated donor transplantation for chronic myelogenous leukemia (CML), chronic phase (CP), accelerated phase (AP), and blast crisis (BC) performed after 1992, at the FHCRC, Seattle.

important variables include the type of donor used (related or unrelated), the source of the stem cell product (marrow or peripheral blood), and the age of the patient. Outcomes are superior for HCT in chronic phase compared with advanced phases of disease. In a Seattle analysis of 58 patients with accelerated-phase CML who received transplants from HLA-identical siblings, the 4-year probabilities of survival and event-free survival were 49 and 43%, and the probability of relapse was 12%. The outcome of transplantation for patients in blast crisis is uniformly poor, resulting in a high rate of disease recurrence and transplant-related deaths with event-free survivals of 43%, 18%, and 11% at 100 days, 1 year, and 3 years, respectively. Before the development of imatinib, only a small proportion of patients with blast-phase CML (generally, patients with lymphoid blast crisis) could achieve a hematologic remission with chemotherapy. Transplantation for patients with CML in remission after a previous blast phase results in cure rates somewhat worse than those seen in chronic-phase patients. Response rates of patients with CML in blast phase to imatinib are considerably higher than those seen with conventional chemotherapy. These responses tend to be short, particularly in the setting of lymphoid blast crisis. Limited data are available on the outcome of transplantation for patients with previous blast crisis who are once again in remission following treatment with imatinib, but these few patients seem to have a progression-free survival at 3 years of over 50%.

Preparative regimens have improved incrementally. The majority of patients treated in the early 1980s received a preparative regimen of 120 mg/kg CY, followed by total body irradiation (TBI). Tutschka and colleagues later described the use of 16 mg/kg BU administered over 4 days combined with 60 mg/kg CY on each of 2 successive days, in myeloid malignancies. In 1988 a randomized trial of BU/CY versus CY/12 Gy TBI in myeloid malignancies showed no differences between the CY/TBI and BU/CY treatment groups in survival at 3 years (80%), relapse (13%), or event-free survival (68% for CY/TBI and 71% for BU/CY). An update of this study shows overall survival of 78% at 10 years with BU/CY versus 64% with CY/TBI. The absorption and metabolism of busulfan varies considerably from patient to patient, and busulfan assays were incorporated into transplant trials. Patients with a steady-state busulfan concentration less than the median value (<917 ng/mL) of the cohort had a significantly higher risk for disease recurrence and worse overall survival than those with levels greater than 917 ng/mL. A subsequent report of 131 consecutive CML chronic-phase patients who received transplants from HLA-identical relatives showed a 3-year survival of 86%, a relapse rate of only 8%, and a nonrelapse mortality rate of 14%. Surprisingly, there were no significant differences in outcome related to patient age up to 65 years of age.

Only approximately one-third of patients have HLA-matched family members to serve as donors. Although early results with matched unrelated donor transplantation in CML showed results somewhat poorer than those seen with matched siblings, advances in donor selection, graft-versus-host disease (GVHD) prophylaxis, and supportive care have resulted in continued improvements in outcome. Thus in many institutions, results following unrelated transplants are almost equivalent to those seen with matched siblings (with a caveat that unrelated donor transplants have a lower-age patient exclusion), and registry data of multiple centers report 65% survival at 5 years among younger patients transplanted within a year of diagnosis.

Marrow was used as the stem cell source in all initial transplant studies. Two large randomized trials involving a variety of hematologic malignancies have shown that use of filgrastim (G-CSF)–mobilized peripheral blood hematopoietic cells leads to more rapid myeloid and platelet recovery when compared with marrow, with no significant difference in acute or chronic GVHD and an overall survival advantage. Although there was a trend toward improved survival in CML patients with the use of peripheral blood, it should be noted that these studies were not prospectively designed to address the role of peripheral blood versus marrow for individual disease states. Furthermore, the results of a randomized study of chronic-phase CML showed no statistically significant differences in outcome between the marrow and peripheral blood groups, though relapse rates were lower in the peripheral blood group and chronic GVHD occurrence was higher compared with patients transplanted with marrow.

Several studies have shown that an increased interval from diagnosis to transplant is associated with a worse transplant outcome, for patients treated in chronic phase. No single cause of failure is markedly increased with delay; rather there is a modest effect of delay on relapse rate and nonrelapse mortality. Thus the delay effect may be due in part to the advancing disease over time and/or the effect of the cumulative toxicity of prior therapy. An IBMTR report suggested that exposure to low-dose busulfan led to a worse outcome with subsequent transplantation. Reports have suggested that exposure to IFN might worsen the outcome of unrelated donor transplant, but data on the effect of IFN on matched-sibling transplantation were less clear. In a recent German report, the 5-year survival rate from transplant was 46% for the 50 patients who received IFN within the last 90 days before transplant and 71% for the 36 patients who did not. These observations suggest that IFN should be avoided, if possible, in the months immediately preceding allogeneic hematopoietic cell transplantation.

The form of GVHD prophylaxis used in the treatment regimens also influences the outcome of transplantation for CML, especially in chronic phase. Prevention of GHVD by removing T cells from the donor marrow was explored in a number of transplant studies in the 1980s. Although successful in reducing the incidence of GVHD, T-cell depletion in CML was associated with high rates of graft failure and relapse, leading to poorer disease-free and overall survival. These findings illustrated the critical role of the graft-versus-leukemia (GVL) effect in eradicating CML following allogeneic transplantation. Because of these observations, T-cell depletion was largely abandoned as a method to control GVHD in CML transplants. However, there has been renewed interest in the possibility of preventing GVHD without loss of a GVL effect by combining T-cell depletion with an intensified conditioning regimen and delayed reinfusion of viable donor lymphocytes.

Several studies have investigated the effect of prior imatinib and transplant outcomes. Early reports warned of an increase in regimen-related toxicity and mortality, especially from hepatic causes. Larger studies have failed to show a deleterious effect of pretransplant imatinib (Fig. 66-11). A study of only CML patients showed no difference in regimen-related mortality, survival, or relapse between 140 patients who received imatinib versus 200 historical controls. Curiously, in a few studies, the incidence of chronic GVHD has been significantly lower in patients receiving imatinib before transplant. However, an analysis from the CIBMTR of CML patients undergoing allogeneic transplantation showed that the cumulative incidence rates of acute and chronic GVHD and treatment related mortality (TRM) were not affected by prehematopoietic stem cell transplantation (SCT) IM exposure. On multivariate analysis conventional prognostic indicators remained the strongest determinants of transplant outcomes.[27] The biology underlying this effect is unknown. Allogeneic transplantation appears to be an effective treatment for T315I-mutated leukemias, providing acceptable survival rates with long-term control of the malignancy without detectable residual disease in some cases.[28]

In the period before the advent of tyrosine kinase inhibitors, allogeneic transplant was the front-line treatment of choice for CML, especially for younger patients. With the firm establishment of imatinib and other tyrosine kinase inhibitors as front-line therapy for CML with excellent outcomes on long-term follow-up, the number of patients undergoing allogeneic transplantation has declined dramatically. Currently, allogeneic transplantation is recommended for those patients in whom a second-generation TKI has failed, patients with TKI-resistant mutations such as T315I, and patients in accelerated phase or blast phase. The MD Anderson group reported outcomes of imatinib-resistant CML patients (chronic phase, $n = 34$; accelerated phase, $n = 9$; and blast crisis, $n = 4$) who underwent allogeneic transplantation. Nineteen patients (40%) had BCR-ABL mutations, 15 of whom had advanced disease. Thirty-two patients (68%) had a major molecular response after transplantation, with a

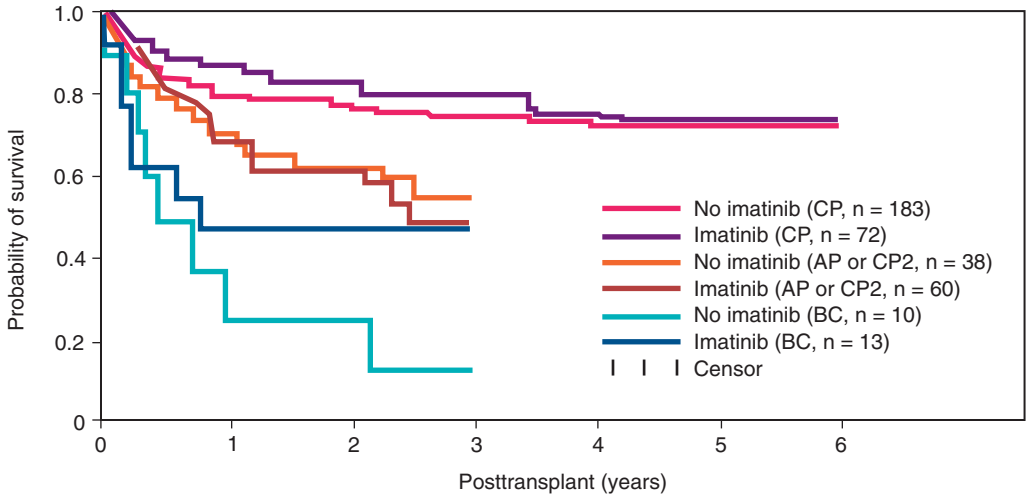

Figure 66-11 EFFECT OF PRIOR TREATMENT WITH IMATINIB ON OVERALL SURVIVAL AFTER TRANSPLANTATION. *CP2,* A return to chronic phase after treatment for accelerated phase or blast crisis disease. *(Data from Oehler VG, Gooley T, Snyder DS, et al: The effects of imatinib mesylate treatment before allogeneic transplantation for chronic myeloid leukemia,* Blood *109:1782, 2007.)*

2-year EFS of 36% and 58% for the mutant and nonmutant groups and a 2-year OS of 44% and 76%, respectively. These results confirm the effectiveness of transplantation as salvage treatment for TKI-resistant patients.[29] Since patients with mutations are more likely to develop advanced disease and have worse outcomes after transplantation, this procedure should be considered early for patients with poor response to a second-generation TKI.

Graft Versus Leukemia Effect in Chronic Myeloid Leukemia

Although evidence for a GVL effect can be found in many settings, nowhere is it as strong as in the setting of allogeneic HCT therapy for CML. Evidence in support of such an effect includes the following: the higher rates of relapse following syngeneic and T cell–depleted transplants compared with unmodified allogeneic transplants; the close association between the development of acute and chronic GVHD and freedom from relapse following non–T cell–depleted transplants; and the high response rate to donor lymphocyte infusions to treat posttransplant relapse (range from 50% to 100%), which is higher than in any other malignancy. The markedly increased relapse rates seen with T-cell depletion indicate a role for T cells in GVL. T cell targets might include minor histocompatibility antigens shared by most cells in the body, thus accounting for the association of GVL with GVHD. Alternatively, there may be polymorphic minor histocompatibility antigens, with expression limited to hematopoietic tissue. A third possible category of targets for the GVL effect in CML is the overexpression of protein targets in CML cells. Understanding the cells and their targets responsible for the potent GVL effect seen in CML will be critical to the development of more effective, less toxic transplant-based therapies in the future.

Reduced-Intensity Conditioning

Reduced-intensity conditioning (RIC) or nonablative transplant approaches have been introduced with the aim of avoiding the toxicities of high-dose preparative regimens while retaining GVL effects. These approaches are of particular relevance for patients with CML because their median age at diagnosis is 67 years. Using a preparative regimen consisting only of 200-cGy TBI, and GVHD prophylaxis using cyclosporine (CSP) and mycophenolate mofetil (MMF), McSweeney and colleagues reported complete molecular responses in five of nine patients transplanted for CML in chronic phase ($n = 6$) or accelerated phase ($n = 3$). The other four patients rejected their grafts. By adding 30 mg/m^2 fludarabine pretransplant, graft rejection has been eliminated as a problem following matched-sibling transplantation. Or and colleagues recently reported similar encouraging results using a preparative regimen of fludarabine, low-dose busulfan, and antithymocyte globulin. The MD Anderson group reported outcomes of 64 CML patients with advanced-phase disease (80% beyond first chronic phase), not eligible for myeloablative preparative regimens because of older age or comorbid conditions, who received transplants with fludarabine-based reduced intensity conditioning regimens (matched related, $n = 30$; one antigen-mismatched related, $n = 4$; matched unrelated, $n = 30$).[30] At 5 years, the overall survival (OS) and PFS were 33% and 20%, and TRM was 48%. In multivariate analysis, only disease stage at time of HSCT was significantly predictive for survival. These results indicate that reduced intensity transplantation may offer a safe and effective way to treat CML in the chronic phase, but alternative treatment strategies need to be explored in patients with advanced disease.

Residual Disease Posttransplantation

The detection of BCR-ABL transcripts posttransplant is a strong predictor of relapse following transplantation. In a study of 346 patients after transplantation, 40% of patients were positive for BCR-ABL residual disease at 3 months posttransplant, but this finding was not predictive of outcome, suggesting that eradication of the CML clone posttransplant takes an extended period of time. In contrast, at 6 or 12 months posttransplant, 27% of patients were BCR-ABL–positive and at this time the assay was a powerful predictor of outcome, as only 3% of PCR-negative patients eventually relapsed compared with 42% of PCR-positive patients. The predictive power of PCR detection of BCR-ABL among longer-term survivors is somewhat weaker. At 18 months posttransplant, 1% of 289 BCR-ABL-negative patients subsequently relapsed compared with 14% of 90 BCR-ABL-positive patients. The advent of reliable quantitative PCR testing further refined risk prediction of BCR-ABL detection. Olavarria and colleagues studied 138 transplant patients at 3 to 5 months posttransplant and were able to define patients as having a low risk for relapse (16%), an intermediate risk (43%), or a high risk (86%) based on BCR-ABL quantification. Further studies have confirmed the importance of quantitative BCR-ABL monitoring of minimal residual disease after transplantation for CML, which offers an obvious opportunity for early intervention for patients with residual or recurring disease.

Treatment of Posttransplant Relapse

The pace of disease progression after posttransplant relapse is variable; some patients remain low-level PCR-positive for BCR-ABL for years without relapsing, and some relapse with low levels of Ph-positive metaphases and remain stable for many years. The EBMT retrospectively studied 130 patients who relapsed after transplant before 1990 and noted that postrelapse survival (without DLI or imatinib therapy) was significantly better for recipients of matched-sibling grafts for chronic-phase disease, with a short interval from diagnosis to transplant but a long interval from transplant, with a 42% likelihood of being alive 10 years after posttransplant relapse. An appreciation of the likely tempo of progression is thus important when considering treatment intervention options.

An increasing number of potential interventions are available for relapsing disease. IFN can produce both clinical and cytogenetic remissions in patients who have relapsed after transplantation. Results with IFN appear better if treatment is initiated at the time of cytogenetic relapse instead of waiting until hematologic relapse, because IFN induces molecular remissions in some individuals treated early. A large number of studies now demonstrate cytogenetic complete response rates of 50% to 100% in patients treated with DLI for clinically relapsed chronic-phase CML. Response rates tend to be higher for patients treated earlier at the time of cytogenetic relapse and lower for patients in accelerated phase. The two major complications of DLI are transient marrow failure and the development of GVHD. Marrow failure only occurs in patients treated in hematologic relapse and likely reflects clearance of host hematopoiesis before donor hematopoiesis recovers; this is of particular concern for patients in full-blown hematologic relapse with no evidence of residual donor hematopoiesis. Treatment earlier in the course of relapse can avoid this complication. The overall incidence of GVHD following DLI is approximately 50% in most series. Most early studies of DLI involved a single infusion of a relatively large number of donor T cells. It has since been reported that large numbers of T cells are tolerated with less GVHD if administered in a fractionated fashion rather than as a single bulk dose. A recent report from the EBMT provides further support for starting at lower doses of lymphocytes and escalating dosage as required.

More recently, imatinib mesylate has been shown to be active as posttransplant therapy. In a recent report of 28 patients who were treated with imatinib for posttransplant relapse, an overall response rate of 79% was seen, with CHR seen in 100% of patients in chronic phase, 83% in accelerated phase, and 43% in blast crisis. CCR was seen in 29% of patients. Recurrence of GVHD disease was seen in 18%, and granulocytopenia requiring dose adjustments of imatinib developed in 43% of patients. Because imatinib has only recently become available, almost all of the reported cases treated with imatinib for posttransplant relapse had never been treated with the drug previously. However, imatinib appears to be tolerated given early after transplantation to prevent relapse in high-risk Ph-positive cases. Twenty-two patients with Ph-positive ALL or advanced-phase CML received imatinib at a median of 28 days postengraftment. Of these patients, 17 of 19 adults and all 3 children tolerated imatinib at the targeted dose (400 mg/day for adults, 260 mg/m^2/day for children), and 19 completed the planned course of 1 year of imatinib therapy. At a median follow-up of approximately 1½ years, 12 of 15 of the Ph-positive ALL and 5 of 7 of the CML patients were in molecular remission.

Autologous Transplantation

The rationale for autologous transplantation in CML has been provided by the experimental and clinical evidence for persistence of polyclonal Ph-negative progenitors capable of reconstituting hematopoiesis in CML patients. This is most dramatically demonstrated by the high rate of cytogenetic and molecular response in CML patients treated with tyrosine kinase inhibitors. Furthermore, it was shown that transplantation of autologous cells may allow restoration of Ph hematopoiesis. Initial studies carried out using unmanipulated autologous marrow or blood cells indicated that autologous transplantation could reestablish CP in patients with advanced disease and induce cytogenetic responses in a small proportion of CML CP patients. Subsequent studies indicated that depletion of Ph-positive progenitors by ex vivo graft manipulation was associated with cytogenetic remission posttransplant. Another approach to depleting

Management of the Newly Diagnosed Chronic Myeloid Leukemia Patient

What should be the initial management for CML patients? After years of clinical research, we know (a) imatinib is remarkably effective for patients treated in chronic phase, because greater than 85% of patients obtain a complete cytogenetic response and approximately 70% of cases remain in CCR at 5 years of follow-up; (b) second-generation tyrosine kinase inhibitors, dasatinib and nilotinib, used as first-line treatment for chronic phase CML may be even more effective, resulting in faster and more profound reduction in BCR-ABL levels; (c) allogeneic transplantation is generally associated with 10-year survival rates of 70% or better for younger patients in early chronic phase; and (d) outcome for patients receiving TKI treatment can be effectively monitored by sensitive RT-PCR assays.

Imatinib has become the initial treatment of choice for patients with CML. For patients diagnosed during chronic phase, imatinib is a reasonable first choice of therapy. However, in view of the association between cytogenetic and molecular responses on imatinib and survival, it is reasonable to suggest that the faster and deeper reduction in disease burden using the second-generation agents may reduce the risk for progression when compared with imatinib. The tolerability of the newer agents appears to be comparable to imatinib, although follow-up is shorter and the long-term effects of treatment are not known. It is notable that differences in overall survival have not been observed as yet. In addition, low-risk chronic-phase patients demonstrate excellent survival with imatinib. In addition, imatinib is considerably less expensive than the newer agents and a generic form will soon be available, reducing costs further. Careful monitoring of imatinib response could potentially identify the subset of patients who will benefit from second-generation tyrosine kinase inhibitor treatment. Longer-term follow-up of patients from the front-line studies and better prognostication measures for response to individual agents will be required to resolve these issues. Until then, the choice of first-line TKI is dependent on individual preference based on risk group, toxicity profile, dosing schedule, and economic factors.

For patients with chronic-phase disease, tyrosine kinase treatment can be initiated with simultaneous workup of family donors and unrelated donors. Criteria for failure or suboptimal response have been developed. Certainly, the failure of imatinib treatment to achieve a complete hematologic response at 3 months of treatment, lack of any cytogenetic response by 6 months, or lack of a major cytogenetic response by 12 months is an indication to switch therapy. By a conservative approach, patients should achieve a complete cytogenetic response by 18 months of therapy. Similarly, BCR-ABL mRNA levels greater than 10% at 6 months and greater than 1% at 12 months (using the international scale) are indicators to switch treatment. Patients who relapse after a CCR, especially those with ABL point mutations, should consider alternative therapy, including transplant. For patients diagnosed in accelerated phase or in blast crisis, initial treatment with dasatinib results in better responses than those seen with imatinib, but in general, these responses tend to be short-lived; thus advanced-phase patients should consider transplantation as soon as possible.

malignant cells from the graft was to treat patients before harvesting marrow or peripheral blood for transplantation, also called *in vivo purging*. However, remissions following autologous transplantation were usually of short duration. In addition, the procedure was often associated with significant toxicity and delayed recovery. Although the compiled results of 200 autologous transplants at eight different centers in Europe and North America indicated a possibility of improved survival, it is not possible to make any definite conclusions in the absence of controlled clinical trials. A meta-analysis of six trials in which patients were randomly allocated to receive autologous HCT or an IFN-based regimen did not show an advantage for HCT.

Autologous HCT has now fallen out of favor in view of the excellent results of tyrosine kinase inhibitor treatment in CML patients. Pilot studies to collect PBSC from patients who have received imatinib and achieved CCR, for use for autologous HCT in case of later progression, have been reported. The PBSC collection process is well tolerated and Ph-negative collections are more consistently achieved than with previous strategies. Although the target numbers of $CD34^+$ cells is usually attained, a subset of patients are unable to reach this target. Furthermore, many patients mobilize suboptimally and require multiple collections, possibly as a result of the effects of imatinib on normal hematopoiesis and the mobilization process. Collections are usually Ph-negative, but molecular evidence of disease is usually found. Collection of PBSC from patients responsive to tyrosine kinase inhibitors may form the framework of any future attempts to perform autologous transplantation in CML; however, additional strategies are needed to further deplete leukemia cells from PBSC collections and to improve therapy for residual disease posttransplant. At this point, autologous HCT for CML should be limited to investigational trials for patients who lack allogeneic donors and for those in whom tyrosine kinase inhibitors have failed (see box on Management of the Newly Diagnosed Chronic Myeloid Leukemia Patient).

CHAPTER 67

THE POLYCYTHEMIAS

Marina Kremyanskaya, Vesna Najfeld, John Mascarenhas, and Ronald Hoffman

Under normal conditions, the red blood cell (RBC) mass in humans is tightly controlled and remains relatively constant in a given individual. The numbers of senescent RBCs lost daily are replaced by newly formed ones by a carefully controlled network of growth factors and progenitor cells. Erythropoiesis can be augmented by a variety of stimuli that increase the delivery of oxygen to tissues. This delicate balance can be disturbed by various pathologic conditions and can result in either reduced numbers of RBCs (anemia) or excessive numbers of RBCs (polycythemia). Hematocrit values over 52% in males and over 48% in females are abnormal and require further evaluation to determine if the patient has an absolute increase in the RBC mass and investigation of its cause. The RBC mass is defined as being increased if it is greater than 125% above that expected for sex and body mass. The measurement of the RBC mass is a diagnostic study that is now available at a dwindling number of tertiary care centers, making other diagnostic studies pivotal in evaluating patients with elevated hematocrit levels. Polycythemic states can be caused by a variety of disorders that can be attributed to several pathophysiologic mechanisms. Determination of the etiology of an individual's polycythemia is a critical step in defining the patient's appropriate prognosis and treatment plan. Primary polycythemias are the result of innate abnormalities involving hematopoietic progenitors and stem cells that lead to constitutive overproduction of RBCs, which are accompanied by low erythropoietin (EPO) levels. By contrast, secondary polycythemias are the consequence of a number of conditions that lead to increased EPO production, which acts on normal progenitors to overproduce RBCs. In a small number of patients, the cause of erythrocytosis cannot be determined; these patients are classified as having idiopathic erythrocytosis (IE). Approximately one-third of these patients have low EPO levels; the remainder have inappropriately normal or elevated EPO levels. This latter group presumably has a secondary form of erythrocytosis, although a mechanism leading to the absolute erythrocytosis is frequently not defined.

ERYTHROPOIESIS

Red blood cell production can be influenced by numerous factors, including nutrients, growth factors, numbers and function of bone marrow (BM) progenitor and precursor cells, and cellular receptors and transcription factors. The hematopoietic growth factor EPO is considered to be the physiologic regulator of the terminal phases of erythropoiesis. Alterations in its production are followed by adjustments in the rate of formation of RBCs. In humans, EPO production is controlled by the relative supply of oxygen to the kidneys, the major site of EPO. In states of severe hypoxia, EPO production can be increased up to 1000-fold. A large body of information is available addressing EPO physiology in patients with erythrocytosis. After phlebotomy of a healthy person, EPO excretion increases, and an inverse logarithmic relationship between hematocrit and EPO excretion rates is observed. Patients with secondary erythrocytosis caused by chronic hypoxia have either normal or increased basal values, but they also have increased values after reduction of the hematocrit to normal levels by phlebotomy. By contrast, EPO excretion is invariably subnormal in patients with polycythemia vera (PV), which demonstrates that this disorder is not a result of excessive EPO production.

Different levels of EPO are required at the erythroid precursor and progenitor cell levels. In addition, multipotent myeloid progenitors and primitive erythroid progenitors (burst-forming units–erythroid [BFU-E]), both of which ultimately contribute to erythropoiesis, require additional growth factors such as stem cell factor (SCF), interleukin-3 (IL-3), granulocyte macrophage-colony stimulating factor (GM-CSF), or thrombopoietin (TPO) to promote their proliferation and maturation. In addition, erythroid cell proliferation is also controlled by nuclear receptors such as the glucocorticoid receptor. Glucocorticoids have been shown to maintain erythroblasts in a proliferative state, blocking their terminal maturation in response to EPO and stem cell factor.

ERYTHROPOIETIN, OXYGEN SENSING, AND HYPOXIA-INDUCIBLE FACTOR

Under normal conditions, EPO production is mediated by the decreased oxygen content of hemoglobin within RBCs, termed *hypoxemia,* which leads to decreased oxygen delivery to tissues. Regulation of oxygen homeostasis is critical to survival. In humans, oxygen sensing occurs at many levels, leading to both acute and chronic adaptation. The acute reduction of the availability of oxygen leads to the initiation of a cascade of adaptive events that sets in place compensatory events to correct the lack of oxygen supply. Low oxygen levels, or hypoxia (60 mm Hg), in humans cause oxygen-sensing chemosensory cells to undergo rapid membrane depolarization within seconds, leading to the production of action potentials, influx of calcium ions, and release of the neurotransmitters that result in stimulation of the brain stem that controls the respiratory and cardiovascular systems.[1] These chemosensory cells are found within the glomus cells of the carotid body located at the bifurcation of the internal and external carotid arteries. The released neurotransmitters activate the nerve endings of the carotid body sensory nerve to convey to the central nervous system signals that command ventilation to fight hypoxia, resulting in an increase of the lung ventilation rate and restoration of normal oxygen tension to vital organs. In addition, there are changes in blood pressure and heart rate to maximize oxygen delivery. The carotid body is the organ with the greatest blood flow within the body. Activation of the carotid body results in the sensation of breathlessness experienced by individuals at high altitudes. During chronic hypoxia when the carotid body is permanently active, there is marked enlargement of the carotid body because of an increase in capillaries and a marked reduction in the mean distance from the capillaries to the edge of the chemoreceptor cells.

In response to chronic hypoxia, multiple compensatory mechanisms come into play over several days in the kidneys, the major site of EPO production. Hypoxic stimulation results in production of hypoxia-inducible factor-1 (HIF-1), the major factor responsible for transcriptional activation of the EPO gene. Analysis of proteins that bind to the EPO enhancer under hypoxic conditions led to the identification of HIF. The HIF transcriptional system is a master

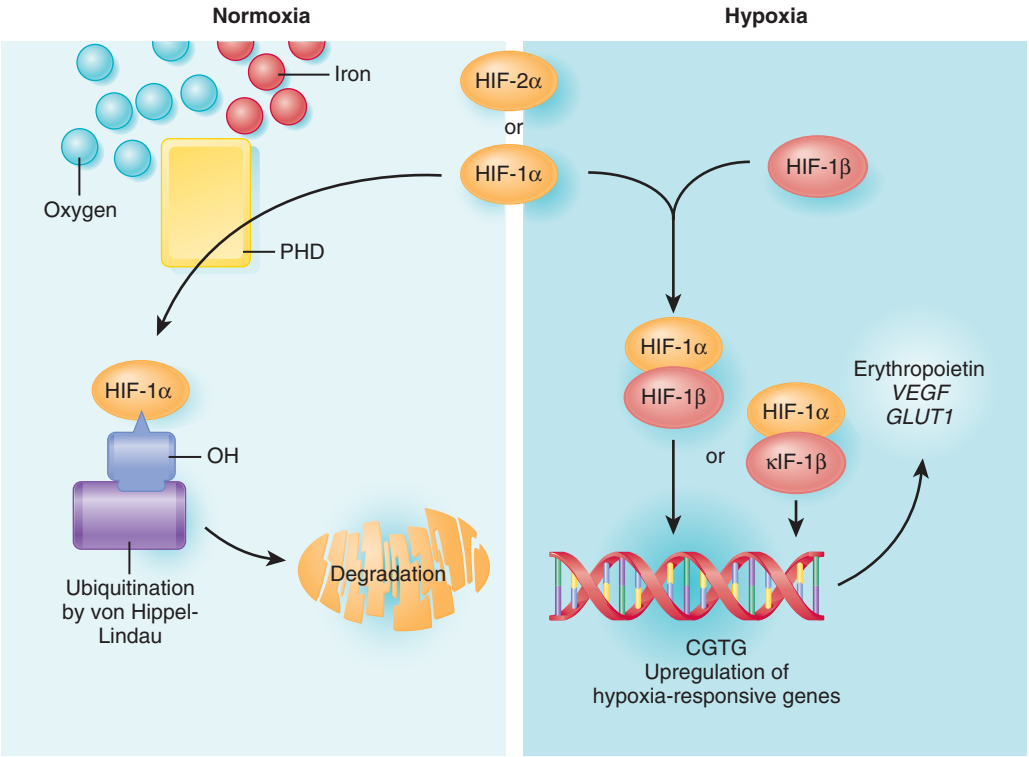

Figure 67-1 SCHEMATIC REPRESENTATION OF THE RELATIONSHIP BETWEEN HYPOXIA SENSING AND ERYTHROPOIETIN PRODUCTION. *GLUT,* Glucose transporter 1; *HIF,* hypoxia-inducible factor; *PHD,* proline hydroxylase; *VEGF,* vascular endothelial growth factor.

regulator of the hypoxic response controlling a large number of genes in multiple cell types. HIF-1 is a heterodimeric protein consisting of HIF-1α and HIF-1β, which is required for normal development of the heart, blood vessels, and blood cells.[2] The levels of HIF-1α increase exponentially as the oxygen concentration declines. As the key mediator of cellular oxygen maintenance, HIF-1 facilitates body oxygen delivery and responses to oxygen deprivation by regulating the expression of gene products that are involved in cellular energy metabolism and glucose transport, angiogenesis, erythropoiesis and iron metabolism, pH regulation, apoptosis, cell proliferation, and cell–cell and cell–matrix interactions. Classic HIF target genes include phosphoglycerate kinase, glucose transporter-1, vascular endothelial growth factor (VEGF), and EPO. The HIF proteins are members of the Per–ARNT–Sim family of heterodimeric basic helix–loop–helix transcription factors (Fig. 67-1).

In contrast to the constitutively expressed, HIF-1β subunits, HIF-1α is an oxygen-labile protein that becomes stabilized in response to hypoxia. HIF-1α mRNA and protein levels are induced by hypoxia, and HIF-1α protein levels decay rapidly with return to normoxia. The posttranslational regulation of HIF-1α protein accounts for the majority of the regulation of this gene. Normoxia-induced, ubiquitin-mediated degradation of the HIF-1α protein is the major regulator of HIF-1α levels, thereby reducing the stimulus for additional EPO production. The targeting and subsequent polyubiquitination of HIF-1α require the von Hippel-Lindau (VHL) protein, oxygen, and three different iron-requiring proline hydroxylase enzymes (PHD) (see Fig. 67-1). The PHD proteins exist in three isoforms, PHD1, PHD2, and PHD3. HIF-1α is hydroxylated by all three isoforms but primarily by PHD2.The prolyl hydroxylation of HIF-1α is necessary for the binding of HIF-1α to VHL, which is the substrate-recognition subunit of an E3 ubiquitin-protein ligase. Different parts of the HIF-1α chains have different functions. The amino terminus part of HIF-1α is involved in DNA binding and dimerization, and the carboxy terminus portion has regulatory functions. One domain at the carboxy terminus influences transcriptional activity without affecting HIF-1α protein levels, and the other region, termed the oxygen-dependent degradation domain (ODD), affects protein abundance. The ODD is divided into an amino terminus and a carboxy terminus subdomain. The VHL protein physically interacts with the ODD of HIF-1α, targeting it for ubiquitination and destruction by the proteasome. Iron-chelating drugs can also block the interaction of HIF-1α with the VHL protein, suggesting a role for iron in the degradation of HIF-1α.

Under normoxic conditions, hydroxylation of HIF-1α is essential for HIF proteolytic degradation by promoting interaction with the VHL tumor-suppressor protein through hydrogen bonding to the hydroxy proline-binding pocket in the VHL-β domain. As oxygen levels decrease, hydroxylation of HIF decreases, and HIF-1α then no longer binds VHL. As a result, it becomes stabilized, dimerizes with HIF-1β, and activates transcription of target genes. The activity of PHDs depends on the availability of molecular oxygen, which qualifies these enzymes as oxygen sensors. In addition, these dioxygenases require 2-oxoglutarate as a cosubstrate and vitamin C to keep their central nonheme iron in the ferrous state. Although PHD-2 appears to be the hydroxylase that is essential for HIF-1α degradation under normoxic conditions, PHD-3 is important for hydroxylation of HIF-1α during reoxygenation. Different effects of individual PHDs on HIF-1α and HIF-2α hydroxylation indicate that the stability of individual HIF-1α subunits and their target gene expression might be affected by tissue- and cell-type differences in PHD expression and activity levels. The activity of PHDs can be modulated by mitochondrial reactive oxygen species, implicating mitochondria in oxygen sensing. Another protein termed HIF-2α has been identified that under hypoxic conditions dimerizes with HIF-1β and activates the transcription of a set of target genes that overlap with the target genes regulated by HIF-1α /HIF-1β heterodimers. HIF-1α is expressed by all nucleated cells, but HIF-2α is expressed by specific cell types, including vascular endothelial cells, renal interstitial cells, hepatocytes, cardiomyocytes, and astrocytes. HIF-2α appears to play a critical role in regulating EPO production in adult mammals, and HIF-1α is also important during yolk sac erythropoiesis. HIF-1 also controls the absorption and delivery of iron to the BM through its repression of hepcidin and activation of genes encoding transferrin and the transferrin receptor.

von Hippel-Lindau syndrome is a hereditary cancer syndrome that is associated with exaggerated responses to hypoxia caused by posttranslational abnormalities in HIF.[3] VHL syndrome is characterized by a propensity for developing clear cell renal carcinomas, retinal hemangioblastomas, cerebellar and spinal hemangiomas, pancreatic and renal cysts, islet cell tumors of the pancreas, and pheochromocytomas. The tumors result from somatic mutations that cause a loss of heterozygosity (LOH) of the *VHL* gene. VHL disease affects approximately one in 35,000 individuals and is transmitted in an autosomal dominant manner. Individuals with VHL disease carry one wild-type VHL allele and one inactivated VHL allele. This inactivation can occur by somatic mutation or hypermethylation. Tumor or cyst development is linked to somatic inactivation or loss of the remaining wild-type VHL allele. Approximately 20% to 37% of VHL patients have large or partial germline deletions, 23% to 27% have nonsense or frame-shift mutations, and 30% to 35% have missense mutations. More than 150 different VHL mutations linked to VHL disease have been reported. The tumors linked to VHL inactivation are often highly vascular and can produce angiogenic factors such as VEGF. In addition, renal cell carcinoma, cerebellar hemangioblastomas, and pheochromocytomas have been associated with paraneoplastic erythrocytosis caused by overproduction of EPO. Overproduction of HIF-inducible mRNAs is the hallmark of VHL protein defective cells. Genotype–phenotype correlates in VHL disease suggest that VHL has functions independent of HIF regulation that might play a role in tumor formation. VHL protein has other binding partners, including atypical protein kinase C and a family of deubiquitinating enzymes named VHL-interacting deubiquitinating enzymes 1 and 2. In addition, pVHL has been involved in numerous cellular processes, including regulation of extracellular matrix, cytoskeleton stability, cell cycle control, and differentiation. VHL disease is not associated with erythrocytosis.

THE ERYTHROPOIETIN RECEPTOR

Interaction of EPO with the EPO receptor (EPOR) present on the erythroid progenitor and precursor cells leads to its homodimerization, resulting in (1) stimulation of cell division, (2) differentiation by induction of erythroid-specific gene expression, and (3) prevention of erythroid progenitor and precursor cell apoptosis. The cytoplasmic portion of the EPOR contains a positive regulatory domain that interacts with Janus kinase 2 (JAK2) (Fig. 67-2). Immediately after EPO binding, JAK2 phosphorylates itself, the EPOR, and other proteins such as STAT5 (signal transducer and activator of transcription 5). This JAK2–STAT5 signaling plays an essential role in EPO/EPOR-mediated regulation of erythropoiesis. Consistent with their essential roles in erythropoiesis EPO, EPOR- and JAK2-deficient mice die embryonically from severe anemia.

The C-terminal cytoplasmic portion of the EPOR also possesses a negative regulatory domain. Hematopoietic cell phosphatase (HCP, also known as SHP-1 or PTP N6) interacts with this portion of the EPOR and downregulates signal transduction by promoting dephosphorylation (see Fig. 67-2). Inactivation of the HCP-binding site leads to prolonged phosphorylation of JAK2–STAT5. Another negative regulator of erythropoiesis, suppressor of cytokine signaling-3 (SOCS-3), binds to the cytoplasmic portion of the EPOR and suppresses EPO-dependent JAK2–STAT5 signaling. Thus deletion of the distal C-terminal cytoplasmic portion of the EPOR abolishes negative regulatory elements and results in increased proliferation of erythroid progenitor cells. Mutations in the *EPOR* gene have been observed in some patients with primary familial and congenital polycythemia (PFCP) and are occasionally found in erythroleukemia (see Fig. 67-2). Such secondary growth factors as insulin-like growth factor-1 (IGF-1) and the components of the renin–angiotensin system (RAS) may also influence the production of RBCs.

THE RENIN–ANGIOTENSIN SYSTEM AND HEMATOPOIESIS

The RAS regulates fluid and electrolyte homeostasis and blood pressure and has been hypothesized to also play a role in the regulation of erythropoiesis. The primary function of angiotensin during development is the regulation of tissue growth and differentiation. Angiotensin II (AngII) is a ligand for two distinct receptors, type 1 and type 2 (AT1 and AT2). AT1 appears to play a major role in the regulation of cell proliferation.

The RAS was first postulated to influence erythropoiesis in the 1980s after the use of angiotensin-converting enzyme (ACE) inhibitors to treat hypertension was shown to result in anemia. In animals, increased blood levels of renin (a major regulator of AngII synthesis) were found to result in elevated serum EPO levels and erythrocytosis. In humans, the infusion of AngII also increases serum EPO levels.

The pathway underlying AngII-driven EPO secretion is unknown. However, some investigators have suggested that AngII modulates renal EPO production through changes in renal perfusion and sodium reabsorption. This hypothesis is based on the presumption that reduced oxygen pressure in the kidneys triggers HIF-1α to induce release of EPO. AngII also directly stimulates proliferation of hematopoietic progenitors in vitro, and inhibition of this effect with ACE inhibitors induces apoptosis of erythroid progenitors in renal transplantation patients. ACE-1 knockout mice develop a normocytic anemia that can be fully reversed by infusion of AngII. ACE-related anemia is most pronounced in patients with renal insufficiency or end-stage renal disease and in patients who have received a renal allograft. The pathogenesis of this anemia is not clear, but reduced levels of circulating EPO are not solely responsible, suggesting that there might be other contributing factors. The AT1 receptor is present on erythroid progenitors, and its ligand, AngII, augments EPO stimulation of erythropoiesis. The involvement of JAK2 kinase in AngII signaling suggests that this signal transduction pathway mediated by EPO and AngII might overlap. Postrenal transplant erythrocytosis likely can be accounted for by activation of the RAS.

DEFINITION AND CLASSIFICATION OF POLYCYTHEMIA

The term *polycythemia* is a literal translation from Greek, meaning "too many cells in the blood," and refers to an increase in the RBC mass; it is frequently used interchangeably with the term *erythrocytosis*. Polycythemia may be due to a myriad of causes (Table 67-1). The polycythemias can be classified as relative and absolute. Relative polycythemia is a disorder in which the patient characteristically has a modest elevation of the hematocrit level without an elevated RBC mass but rather because of contraction of the plasma volume. The absolute polycythemias are accompanied by an actual increase in the circulating RBC mass. Polycythemias can also be classified according to the responsiveness of their erythroid progenitor cells to growth factors or the circulating levels of such growth factors. Primary polycythemias are characterized by increased sensitivity of the erythroid progenitors to regulatory growth factors as a result of acquired somatic or inherited germline mutations expressed by hematopoietic progenitor cells (HPCs). In contrast, secondary polycythemias are characterized by an increase in regulatory growth factors, primarily EPO, and normal responsiveness of their erythroid progenitors to these growth factors. These conditions can usually be distinguished by in vitro assays of erythroid progenitor cells, quantitation of serum EPO levels, and detection of somatic JAK2 mutations. In a small number of patients, the cause of erythrocytosis cannot be determined; these patients are classified as having IE.

Table 67-1 Differential Diagnosis of the Polycythemias

Relative or Spurious Polycythemia

1. Decreased plasma volume—reduced fluid intake, marked loss of body fluids (diaphoresis, vomiting, diarrhea, "third spacing")
2. Gaisböck syndrome
3. Overfilling of blood in collection vacuum tubes

Absolute Polycythemia

1. Secondary polycythemia
 - A. Acquired
 - Hypoxia
 - Pulmonary disease
 - Cyanotic congenital heart disease
 - Hypoventilation syndromes: sleep apnea, Pickwickian syndrome
 - High altitude
 - Smokers' polycythemia, hookah polycythemia, carbon monoxide intoxication caused by industrial exposure
 - Postrenal transplantation erythrocytosis
 - Aberrant erythropoietin production
 - Tumors: renal cell carcinoma, Wilms tumor, hepatic carcinoma, uterine leiomyomata, virilizing ovarian tumors, vascular cerebellar tumors
 - Miscellaneous renal and hepatic disorders: solitary renal cysts, polycystic kidney disease, renal artery stenosis hydronephrosis, viral hepatitis
 - Endocrine disorders: Cushing syndrome, primary aldosteronism
 - Androgen use
 - Erythropoietin use
 - B. Congenital Polycythemias
 - Abnormal high-affinity hemoglobin variants
 - Bisphosphoglycerate deficiency
 - Congenital methemoglobinemia
 - Chuvash polycythemia (von Hippel Lindau mutations)
 - Prolyl hydroxylase mutations
 - Hypoxia-inducible factor gene mutations
2. Primary polycythemias
 - Primary congenital and familial polycythemia
 - Polycythemia vera

RELATIVE POLYCYTHEMIA

Individuals with a modestly increased venous hematocrit level that is not accompanied by an increased RBC mass are frequently thought to be polycythemic by imprecise yet widely accepted medical practice. Frequently, these individuals are thought to be polycythemic owing to the lack of appreciation by a clinician of what constitutes the upper limit of normal values for a hematocrit (52% in males and 48% in females). Such individuals frequently prove not to have an absolute polycythemia as defined by an actual increase in the measured RBC mass. *Relative* or *spurious polycythemia* is a term used to describe an elevation of the hematocrit level either caused by an acute transient state of hemoconcentration associated with intravascular fluid depletion or a chronic sustained relative polycythemia caused by contraction of the plasma volume (see Table 67-1).

Transient polycythemias may be a result of acute depletion of the plasma volume from a variety of disorders, including protracted vomiting or diarrhea, plasma loss from external burns, sudden cold exposure or protracted exercise, insensible fluid loss from fever, sepsis, diabetic ketoacidosis, or acute ethanol intoxication. These elevations of hematocrit can be easily corrected by appropriate replacement of intravascular fluids.

Gaisböck syndrome, first described in 1905, is a benign condition observed mainly in obese, hypertensive, middle-aged, male smokers. Alcohol, diuretics, obesity, hypoxia, psychological stress, and excess catecholamine secretion have been identified as possible causes of relative polycythemia. Such individuals can have a chronic modest to moderate elevation of the hematocrit level associated with a normal RBC mass and low plasma volume, which has been attributed to reduced venous compliance, or they can have a high normal RBC mass with either a normal or slightly decreased plasma volume. The primary significance of the identification of a patient with relative polycythemia is the recognition of the increased risk of developing thrombotic vascular events likely caused by excessive smoking, hypertension, and obesity associated with this disease. The optimal therapy is unknown, but treatment is generally directed at correction of the patient's underlying cardiovascular risk factors.

It is also important to emphasize that overfilling of blood collection vacuum tubes can result in pseudopolycythemia, pseudothrombocytopenia, and pseudoleukopenia as a result of inadequate sample mixing. Careful attention to such a seemingly trivial detail can help avoid expensive, unnecessary diagnostic workups.

ABSOLUTE POLYCYTHEMIAS

Primary Familial and Congenital Polycythemia

This is an autosomal dominant disorder. Although PFCP is uncommon, it is more prevalent than polycythemia caused by

high-oxygen-affinity hemoglobin mutants or a 2,3-biphosphoglycerate deficiency. Unlike patients with PV, patients with PFCP lack splenomegaly and do not progress to acute leukemia. It is not unusual for these patients to present with headaches, dizziness, epistaxis, and exertional dyspnea that resolve with normalization of the hematocrit level.[4] An increased incidence of cardiovascular events and premature morbidity and mortality has been reported in some affected members, but many appear to have a benign clinical course. Although clinical symptoms are relieved by phlebotomy, the increased risk of cardiovascular morbidity is not corrected by maintaining a normal hematocrit. Characteristic laboratory findings are (1) an increased hematocrit and RBC mass without an increased leukocyte or platelet count, (2) no activating mutation of JAK2, (3) a normal hemoglobin–oxygen dissociation curve, (4) low serum EPO levels, and (5) in vitro hypersensitivity of erythroid progenitors to EPO. Even though PFCP is present at birth, many affected patients are incidentally diagnosed later in life after the performance of routine blood counts or when evaluated in the context of multiple family members having polycythemia. It is of interest that one individual so affected was an accomplished cross-country skier who had won medals at the Olympic Games. To date, 16 mutations of the EPOR associated with PFCP have been described, leading to a loss in the negative regulatory domain of the EPOR.

The physiologic basis for EPO-mediated activation of erythropoiesis is as follows: EPO activates its receptor by conformational changes of its dimers, leading to initiation of an erythroid-specific cascade of events. The first signal is initiated by the binding of a tyrosine kinase to the EPOR and its phosphorylation and activation of a transcription factor, STAT5, which regulates erythroid-specific genes. This "on" signal is negated by dephosphorylation of the EPOR by HCP, that is, the "off" signal. Truncation of the EPOR leads to a loss in the negative regulatory domain of the EPOR, a binding site for HCP, leading to a gain-of-function mutation of the EPOR (see Fig. 67-2). In addition the negative regulation of erythropoiesis by SOCS-3, CIS and SHIP1 is presumed to contribute to the underlying cause of PFCP.

Recently, alternative explanations for the increased sensitivity of erythroid progenitors to EPO of patients with PFCP have been provided. EPOR downregulation provides another mechanism by which EPO desensitization can occur. EPOR downregulation is a complex process that involves EPOR-induced internalization or ubiquitination and degradation by proteasomes. EPO-induced receptor internalization is an efficient means of rapidly reducing EPO responsiveness. All of the truncated mutants associated with PFCP are associated with failure to internalize the EPOR, contributing to prolonged signaling through the EPOR. The EPOR degradation process removes all of the phosphorylated tyrosine residues in the intracellular domain of the receptor, thereby preventing further signal transduction. The remaining part of the EPO–EPOR complex is then internalized and degraded by lysosymes. The E3 ligase B-transducin repeat containing protein-1 (B-Trcp-1) is responsible for EPOR ubiquitination and degradation. Mutations of the B-Trcp abolish EPOR ubiquitination and degradation, making BaF3 cells expressing the EPORs hypersensitive to EPO. Each of the PFCP mutations involving the EPOR results in the loss of the binding site for B-Trcp-1. These findings suggest that the EPO hypersensitivity in PFCP might not only be attributable to a failure to recruit negative regulators such as phosphatases to inactivate JAK2 but that these mutant receptors are defective in EPO-induced receptor downregulation.

The effect of a truncated EPOR is not always predictable. Some patients who inherit an EPOR mutation are not polycythemic. This observation suggests that undefined environmental or genetic factors may mask the development of polycythemia. Also, the heterogeneity of the polycythemic phenotype observed in a PFCP animal model appears to be strain dependent. This indicates that gene modifiers or epigenetic factors may mask the development of the full PFCP phenotype.

Mutations of genes encoding proteins other than the EPOR account for most cases of PFCP. Mutations of the EPOR have been found in only 10% to 20% of subjects with PFCP. Additional disease-causing genes and their mutations have yet to be identified. In patients with erythrocytosis who are JAK2V617F negative and do not have a JAK2 exon 12 mutation and who have lifelong erythrocytosis associated with a low serum EPO level, a mutational analysis of the EPOR should be pursued.

SECONDARY POLYCYTHEMIAS

Secondary polycythemias can be either congenital or acquired (see Table 67-1). Conditions leading to hypoxia, such as high altitude, cyanotic heart disease, or chronic lung disease, may result in physiologic polycythemia mediated by increased levels of EPO. There are marked variations in EPO levels and the subsequent erythroid response in the face of chronic hypoxia, suggesting that some of these factors may be genetically determined. The same degree of renal tissue hypoxia may induce substantially different levels of EPO production in response to high altitude. It is likely that these individual variations are a function of genetic differences in hypoxia sensing and the hypoxia response pathways; the exact mechanism has been the subject of recent investigations. For purposes of simplicity and clinical diagnostic usefulness, the secondary polycythemic disorders are divided into those that are acquired and those that are congenital. It should be kept in mind that this division, although useful for differential diagnosis, is artificial. Patients with inherited germline mutations, for instance, can develop an EPO-secreting pheochromocytoma or renal cell cancer, and a patient with PV can smoke and have chronic obstructive pulmonary disease (COPD). In other instances, polycythemia caused by a germline mutation can be masked by an acquired environmental factor or another gene-modifying mutation.

Acquired Secondary Polycythemias

Polycythemias of Cyanotic Heart Disease and Pulmonary Disease

Patients with cyanotic heart disease and pulmonary disease frequently have arterial hypoxemia, leading to increased production of EPO and polycythemia. Excessive EPO production occurs when the Pao_2 is sustained below 67 mm Hg as a result of severely impaired pulmonary mechanics. Because patients with severe pulmonary disease and secondary erythrocytosis frequently have elevated plasma volumes, the degree of elevation of the hematocrit level may be modest. Hematocrit levels as high as 65% or rarely 75% have, however, been reported. Moderate elevations of the hematocrit have been estimated to occur in 20% of patients with COPD. Polycythemia in this setting can contribute to pulmonary hypertension, pulmonary endothelial cell dysfunction, reduced cerebral blood flow, hyperuricemia, gout, and an increased risk of venous thromboembolic disease.

Why some patients with pulmonary disease and congenital heart disease develop polycythemia but others do not is not clear. Increased oxygen-carrying capacity may improve oxygen delivery; however, it is not obvious at what hematocrit level the resultant elevation in blood viscosity impairs blood flow to the tissues, leading to a reduction in oxygen uptake. In addition, oxygen uptake to the tissues is markedly influenced by whole blood volume. Thus, whereas the optimal hematocrit level for oxygen delivery is about 45% in normovolemic subjects, it rises to over 60% in hypervolemic states, likely as a result of engorgement of the vascular bed and a decrease in peripheral resistance. Furthermore, chronic exposure to hypoxia leads to respiratory alkalosis that in turn promotes the synthesis of 2,3-bisphosphoglycerate (2,3-BPG), facilitating increased oxygen delivery to tissues.

The practical relevance of an elevated hematocrit level in this clinical situation is whether and at what level it is harmful or beneficial.[5] An extremely elevated hematocrit level may be detrimental to optimal oxygen delivery. Extreme but not moderate polycythemia caused by chronic hypoxia may affect systemic vascular function by altering blood viscosity, vessel wall shear stress, reduced endothelial

cell–derived nitric oxide release, and increasing the secretion of endothelin. Although it is widely accepted that erythrocytotic pediatric patients with cyanotic heart disease are at an increased risk for developing cerebrovascular accidents, the literature provides conflicting data as relates to the prevalence of such events among adults. A 10% to 13.6% prevalence of stroke and transient ischemic attacks (TIAs) has been reported in a cohort of adult patients with cyanotic heart disease, but others have claimed that such events are rare.

Iron deficiency occurs in more than 30% because of the total depletion of iron stores to support erythropoiesis. Microcytic iron-deficient RBCs are rarely found, and despite the iron deficiency, these patients frequently have normal mean corpuscular volumes but high mean corpuscular hemoglobin concentrations, which might maximize the amount of hemoglobin within an individual RBC, thereby maximizing oxygen delivery. In the past, compensatory erythrocytosis was thought to lead to an increased plasma viscosity, leading to a compromised microcirculation, resulting in such symptoms as headache, sluggish mentation, dizziness, blurry vision, muscle weakness, or paresthesias. In reality, such symptoms are rare in patients with chronic compensated secondary erythrocytosis, and the secondary erythrocytosis is viewed as a physiological desirable response to chronic hypoxia. The symptoms delineated above are likely attributable to decreased tissue oxygen delivery rather than hyperviscosity.

The treatment of hyperviscosity secondary to erythrocytosis in cyanotic heart disease with prophylactic phlebotomy was once a core therapeutic strategy but today is rarely used. In fact, phlebotomy has been reported to have harmful rather than beneficial effects in adults with cyanotic congenital heart disease. Many question if the beneficial effects attributed to phlebotomy represented a placebo effect. Because almost one-third of these patients are iron deficient even though their RBC indices do not reflect this, routine assessment of the patient's iron status is suggested with gradual supplementation with sufficient iron to attain appropriate compensatory levels of erythropoiesis but avoiding excessive sudden increases in the degree of erythrocytosis. The present evidence indicates that prophylactic phlebotomy promotes the development of iron deficiency, decreases exercise tolerance, and increases the number of cerebrovascular events. Currently, experts in this field recommend that phlebotomy should be restricted to individuals with symptoms with extreme erythrocytosis (hematocrit >65%) and preoperatively to improve hemostasis. Clinical data to justify these recommendations are lacking. Phlebotomy must be followed by the infusion of an equal volume of fluids to maintain intravascular volume and blood flow as well as to provide a dilutional effect to reduce the hematocrit level. A 1:1 replacement with 0.9% normal saline has been recommended, but others have suggested replacing the volume of blood removed with 1:1 fresh-frozen plasma infused over 30 to 60 minutes. Hydroxyurea therapy has been used occasionally to reduce erythropoiesis in this situation to reduce the need for phlebotomy, but little evidence exists for this approach. The superiority of hydroxyurea therapy versus phlebotomy therapy has not been documented. Hydroxyurea might act not only by suppressing RBC production but also by promoting macrocytic RBC formation, thereby increasing RBC deformability and decreasing RBC adhesiveness.

Chronic oxygen therapy in patients with severe COPD has resulted in relief of hypoxia and a modest reduction in hematocrit levels. Pharmacologic interventions, including theophylline, inhaled nitric oxidesildenafil, or antagonism of the renin–angiotensin pathway with losartin, may also reduce the degree of pulmonary hypertension or secondary erythrocytosis.

Obstructive Sleep Apnea–Induced Polycythemia

Obstructive sleep apnea syndrome is characterized by repetitive episodes of partial or complete obstruction of airflow during sleep. Common symptoms include loud snoring and breathing pauses observed by a bed partner, feelings of nonrefreshing sleep, and excess daytime sleeping. Although the evidence is largely anecdotal, secondary polycythemia is a widely recognized complication of long-standing sleep apnea, being found in 5% to 10% of those with nocturnal apnea and hypopnea. Similarly, 25% of those with unexplained polycythemia are subsequently found to have sleep apnea. The mechanism by which sleep apnea causes polycythemia is unclear. Differences in EPO levels between normoxic and hypoxemic patients referred for suspected sleep apnea have not been documented. Obstructive sleep apnea is also associated with an increased risk of developing cardiovascular diseases, including systemic hypertension, pulmonary hypertension, cardiac arrhythmias, atherosclerosis, ischemic heart disease, and stroke. Intermittent hypoxia is thought to be a major cause of cardiovascular complications. These patients undergo repeated episodes of hypoxia and normoxia. The hypoxia leads to ischemia, and the reoxygenation causes a sudden increase of oxygen. This reoxygenation phase results in the production of reactive oxygen species and the promotion of oxidative stress, leading to an inflammatory response and the development of vascular complications.

Conversely, PV may induce central sleep apnea by decreasing cerebral blood flow to diencephalic respiratory centers, and patients so affected can have complete resolution of their sleep disorder with normalization of their blood counts.

Pickwickian Syndrome and Polycythemia

Pickwickian syndrome or obesity–hypoventilation syndrome, seen in morbidly obese individuals, is characterized by chronic hypoxemia and hypercapnia caused by alveolar hypoventilation, with a resultant increase in EPO production, polycythemia, and cor pulmonale. The three principal causes are the high cost of the work of respiration in morbidly obese individuals, dysfunction of the respiratory centers, and repeated episodes of nocturnal obstructive apnea. Effective treatments include surgically induced weight loss, nasal continuous positive airway pressure ventilation, and the respiratory stimulant medroxyprogesterone acetate.

Polycythemia Caused by High Altitude

Polycythemia caused by the hypoxic conditions encountered by high-altitude dwellers would appear at first glance to represent a universal adaptive process to altitude. High altitude results in hyperventilation, alkalosis, and shifting of the O_2 dissociation curve to the left, leading to the impaired release of O_2 from hemoglobin and ultimately tissue hypoxia. This tissue hypoxia results in markedly increased EPO production, leading to increased plasma iron turnover, reticulocytosis, and a rising hematocrit level. Residents of the Andes Mountains who live 4200 m above sea level frequently have 30% higher hematocrit levels than individuals living at sea level.

People native to high altitudes (highlanders) live in a hypobaric hypoxic environment characterized by a low ambient partial pressure of oxygen. In response to this environment, they develop alveolar hypoxia, hypoxemia, and polycythemia. Healthy highlanders develop pulmonary hypertension, right ventricular hypertrophy, and an increased amount of smooth muscle cells in the distal pulmonary arterial branches, which leads to increased pulmonary vascular resistance and pulmonary artery pressure as compared with individuals living at sea level. The importance of these structural changes in the pulmonary vasculature in highlanders is confirmed by the slow decline of pulmonary artery pressure, which is normalized after living for 2 years at sea level. Despite these adaptive changes, healthy highlanders are able to perform physical activities similar to or often even more strenuous than those living at sea level. In fact, there are differences in ventilation rates between athletes performing at sea level and those at high altitudes. Ventilation rates of athletes increase normally during exercise at sea level, but relative hypoventilation occurs in highlanders. This relative hypoventilation is characteristic of Andean natives and has been ascribed to desensitization of the carotid bodies to the hypoxic stimulus. The erythrocytosis observed in individuals who reside at high altitudes for relatively short periods of time (days) can also be attributed in part to excessive water loss and contraction

of the plasma volume. Total acclimatization of an individual who moves from sea level to a high altitude may actually require years. Individuals who reside at sea level and are acutely exposed to high altitudes are at increased risks of developing deep venous thrombosis, pulmonary infarction, retinal hemorrhage, and ischemic digits because of increased blood viscosity. High-altitude climbers frequently combat these problems by intravenous administration of isotonic saline, with considerable success.

The chronic responses of various ethnic and racial groups to high altitudes are quite variable. Andean natives, known as the Quechua and Ayamara Indians, experience a gradual increase in their hemoglobin levels with age. In addition, hemoglobin values are almost 10% higher in those living at 5500 m above sea level than in those living at 4355 m above sea level. Curiously, their Tibetan and Ethiopian counterparts living at similar altitudes do not respond to the resultant chronic hypoxia by increasing their hematocrits.[6] It has been suggested that high levels of nitrous oxide in the exhaled breath of Tibetans may improve oxygen delivery by inducing vasodilatation and increasing blood flow to tissues, thus making the compensatory increased RBC volume unnecessary. Interestingly, Tibetans and Ethiopians have lived much longer as mountain dwellers than the Quechua or Ayamara Indians, suggesting that extreme elevation of the RBC mass is a maladaptation that Tibetans and Ethiopians have avoided by adopting more physiologic compensatory mechanisms. Many residents of the Tibetan plateau reside at elevations exceeding 4000 m and experience oxygen concentrations that are about 40% lower than experienced at sea level. Human adaptation to a high-altitude environment has been believed to be the result of advantageous genetic mutations and selective pressure.[7] These genetic adaptations are shared by common ancestors within East Asian but not Central and South Asian populations and confer characteristics including adaptation to hypoxia, the absence of CMS, and high offspring survival rates. Polymorphisms in the *EPAS1* gene that encodes HIF-2α, and the *EGLN1* gene, which encodes PHD2, have been positively selected and have been shown to be associated with the key adaptive features in Tibetans. The putative advantageous haplotypes of *EGLN1* and *EPAS1* have revealed negative correlations with hemoglobin levels in Tibetans compared with lowlander Han Chinese. These Tibetans apparently are able to maintain sufficient oxygenation of tissues at high altitudes without increasing RBC numbers. Variations in *ELGN1* and *EPAS1* have also been linked to susceptibility to developing high altitude pulmonary edema. Other factors can contribute to the development of erythrocytosis in high-altitude dwellers. Many inhabitants of the mining community of Cerro de Pasco (altitude, 4280 m) with excessive erythrocytosis (mean hematocrit, 76%; range 66%–91%) have been shown to have toxic serum cobalt levels, suggesting that other EPO-promoting factors such as cobalt might augment the hypoxia-inducing effect on EPO, causing the extreme polycythemias.

This individual variability of elevation of serum EPO levels in high-altitude dwellers and the resultant increase in RBC mass appears widespread. For example, acclimatization to moderately high altitudes when combined with low-altitude training (so-called living high, training low) improves sea-level performance in endurance athletes, in part because of the erythropoietic effects of altitude exposure. This substantial individual variability in response to all forms of altitude training correlates with improved athletic performance and with elevation of EPO levels. A large component of this individual variability appears to be related to differences in the peak and rate of decay of the increase in EPO in response to altitude exposure. These observations suggest that genetically determined variables account for individual responses to hypoxia.

Chronic mountain sickness (CMS) is a pathological loss of adaptation to altitude by highlanders. CMS is a clinical syndrome that occurs in native or lifelong residents living above 2500 m. Anecdotal reports of families or people being particularly susceptible to CMS are frequently cited as evidence that certain individuals have an innate susceptibility to develop CMS. It is characterized by excessive erythrocytosis (females, Hb >19 g/dL; males, Hb >21 g/dL); severe hypoxemia; and in some cases, moderate or severe pulmonary hypertension that may lead to the development of cor pulmonale and congestive heart failure. The clinical picture of CMS gradually disappears after descending to lower altitudes and reappears after returning to high altitudes. The prevalence of CMS is higher in men than women and increases with altitude, aging, associated lung disease, history of smoking, and air pollution. CMS is a public health problem in populations of mountainous regions of the world living above 2500 m. In China alone, 80 million people live above that altitude, but in South America, 35 million people live above 2500 m. CMS is a common problem in these areas. Bolivian investigators have reported a prevalence of CMS in 6% to 8% of males in La Paz (3600 m) and a hospital frequency of 28%. Chinese investigators have reported an overall prevalence of 5.6% in Chinese Han immigrants and 1.2% in Tibetan natives living in the Qinghai Tibetan plateau. The major mechanism underlying the development of CMS is relative alveolar hypoventilation. Healthy highlanders characteristically hyperventilate. A gradual decline in the rate of alveolar ventilation in these individuals leads to progressive loss of adaptation to chronic hypoxia and the development of CMS. The main components of this syndrome include (1) alveolar hypoventilation leading to relative hypercapnia and increasing hypoxemia; (2) excessive polycythemia leading to increased blood viscosity and expansion of the total lung blood volume; (3) pulmonary hypertension and right ventricular hypertrophy that may evolve to hypoxic cor pulmonale and heart failure; and (4) neuropsychiatric symptoms, including sleep disorders, headache, dizziness, and mental fatigue. Physical examination reveals cyanosis of the nail beds, ears, and lips in contrast to the ruddy color that is characteristic of a healthy highlander. In some cases, the face is almost black, and the mucosa and conjunctiva are dark red. The fingers are frequently clubbed, and auscultation of the heart reveals an increased pulmonary second sound. The patients are frequently hypertensive and have evidence of heart failure. Chest radiographic and electrocardiographic findings are characteristic of right atrial and right ventricular hypertrophy. The cardiac hemodynamic values of patients with CMS and healthy highlanders and those living at sea level are shown in Table 67-2. Criteria for the diagnosis of CMS have been recently published and are useful in identifying CMS patients as well as monitoring their response to treatment.

The definitive treatment for CMS is descent to lower altitudes or sea level. The degree of polycythemia decreases after a few weeks or months, and eventually the hematocrit level returns to sea-level values. Pulmonary hypertension and right ventricular hypertrophy gradually resolve and disappear after 1 to 2 years of living at sea level. Phlebotomy or isovolemic hemodilution can reduce the excessive erythrocytosis and hyperviscosity. A variety of drugs has also been evaluated for the treatment of patients with CMS. Ten weeks of the respiratory stimulant medroxyprogesterone acetate at doses of 60 mg/day led to a reduction of the hematocrit level from 60% to 52% and an increase in arterial oxygen saturation from 84% to 90% in 17 highlanders with excess erythrocytes. Medroxyprogesterone use, however, was associated with a loss of libido in men and therefore is infrequently used in this population. Therapy with almitrine, a respiratory stimulant, or enalapril, an ACE inhibitor (10 mg/day for 30 days), has resulted in even more modest reductions of hematocrit levels. Acetazolamide therapy has been evaluated in a small double-blind, placebo-controlled, randomized clinical trial of patients with CMS. Acetazolamide is an inhibitor of carbonic anhydrase and stimulates ventilation by promoting the development of metabolic acidosis. Furthermore, acetazolamide reduces renal EPO production. Patients with CMS were randomized to receive placebo or acetazolamide therapy at a dose of 250 or 500 mg/day for 21 days. Drug therapy at both doses of acetazolamide resulted in reduction of hematocrit levels by 7% ($P < .001$) and serum EPO levels by 50% to 67% ($P < .1$), with an increase in nocturnal oxygen saturation levels of 5% ($P < .01$). According to this small study, 250 mg of acetazolamide daily appears to be an inexpensive, nontoxic, effective therapy for CMS. Whether this conclusion can be validated by larger clinical trials and can be implemented successfully in large populations of patients with CMS has yet to be determined.

Table 67-2 Frequency of JAK2V617F Mutations in Polycythemia Vera, Essential Thrombocytosis, and Primary Myelofibrosis

	JAK2V617F Detection Method	PV: JAK2V617F (Homozygous)	ET: JAK2V617F (Homozygous)	PMF: JAK2V617F (Homozygous)
James et al	Sequencing	89 (30)	43	43
Levine et al	Sequencing	74 (25)	32 (3)	35 (9)

ET, Essential thrombocytosis; *PMF,* primary myelofibrosis; polycythemia vera.

Smokers' Polycythemia or Carbon Monoxide–Induced Polycythemia

Smoking is the most common cause of secondary polycythemia. Those affected have a carboxyhemoglobin-induced increase in RBC mass or decrease in plasma volume, either of which is reversible with smoking cessation. Excessive carbon monoxide exposure can also be attributed to exposure to industrial emissions and automobile exhaust. Carbon monoxide binds to hemoglobin with a more than 200 times greater affinity than oxygen, resulting in not only occupation of one of the heme groups of hemoglobin but also an increase in the O_2 affinity by the remaining heme group. Individuals smoking even one pack of cigarettes a day frequently have elevated hematocrit levels. These patients characteristically have normal blood gases and elevation of carboxyhemoglobin levels, resulting in a reduction in $P_{50}o_2$. The elevation of the hematocrit level is reversed with the interruption of the smoking behavior. Increased hematocrit levels have been observed in 3% to 5% of heavy smokers. Although these patients are not immune to thrombotic complications, the number of thromboembolic events is lower than in patients with PV. A retrospective review of patients with either PV or smokers' polycythemia found that 60% of those with PV had thromboses, but only 41% of those with smokers' polycythemia were so affected (P <.05). Recently, polycythemia has also been reported to be associated with hookah use. A hookah is an oriental pipe containing tobacco often mixed with molasses and fruit flavors connected by a long flexible tube that draws the smoke to the bowl of water. Hookah use exposes the user to generous amounts of carbon monoxide, resulting in erythrocytosis.

Postrenal Transplantation Erythrocytosis

Postrenal transplantation erythrocytosis (PTE) is defined as a persistently elevated hematocrit level greater than 51% after renal transplantation without an elevation of the WBC (WBC) count or platelet count. PTE is a potentially dangerous condition found in approximately 10% to 15% of renal allograft recipients. PTE usually develops within 8 to 24 months after a successful renal transplantation and resolves spontaneously within 2 years in about 25% of patients despite persistently good renal allograft function. PTE is more common in males and may recur in the same patient after a second successful renal transplantation. Factors that increase the likelihood of its development are a lack of EPO therapy before transplantation, a history of smoking, diabetes mellitus, transplant-related renal artery stenosis, retention of the native kidney, low serum ferritin levels, and normal or high pretransplantation EPO levels. PTE is also more frequent in patients who do not experience rejection. At higher hematocrit levels (usually >60%), thrombotic events may complicate the clinical course of patients with PTE.

Approximately 60% of patients with PTE experience malaise, headache, plethora, lethargy, and dizziness. In addition, from 10% to 20% develop thromboembolic complications involving either arteries or veins. Retention of the native kidney is essential for the development of PTE in most cases. Although the transplanted kidney produces EPO under normal regulatory mechanisms, the native kidney overproduces EPO despite the development of erythrocytosis. Frequently, the PTE resolves with removal of the native kidney. Plasma EPO levels are higher (10-fold) in patients with PTE than in nonerythrocytotic renal transplant recipients. In addition, erythroid progenitor cells isolated from patients with PTE are hypersensitive to EPO.

The molecular basis of PTE remains unclear; AngII is believed, however, to play an important role in its pathogenesis by sustaining the secretion of EPO. Growing evidence indicates that increased AT1R expression makes erythroid progenitor cells hypersensitive to AngII. Furthermore, AngII can modulate release of erythropoietic stimulatory factors, including EPO and IGF-1. Because men comprise almost all of the transplant recipients who develop PTE, androgens are thought to play a role in the development of the syndrome. Androgens can directly affect erythroid progenitor cells or stimulate EPO production or actually the RAS. Treatment of patients with PTE includes intermittent phlebotomy or administration of drugs. The ACE inhibitor enalapril suppresses the renin–angiotensin pathway and virtually eliminates the need for therapeutic phlebotomy in these patients. Maximal reduction of hemoglobin levels is evident 6 months after starting therapy with either ACE inhibitor or angiotensin receptor blockers. Some patients are exquisitely sensitive to these medications and may become severely anemic. The AT1R antagonist losartan has been shown to be as effective in treating PTE as are ACE inhibitors. Therapy is usually begun at hematocrit levels above 55% with the hope of maintaining hematocrit levels below 50% to reduce the risk of thrombosis. Furthermore, the ACE inhibitor fosinopril in an open-label crossover trial with theophylline was shown to produce a dramatic reduction in hematocrits in patients with PTE (51.3%–43.7%; P <.005). Low doses of ramipril, another ACE inhibitor, normalized the hematocrit level in 26 of 27 patients with PTE after a mean of 127 days of therapy.

Polycythemia Accompanying Kidney and Liver Diseases and Neoplastic Disorders

Polycythemia has been reported in association with kidney diseases such as renal cell carcinoma, renal artery stenosis, hydronephrosis, Wilms tumor, and polycystic kidney disease, paragangliomas, and pituitary adenomas. Renal tumors account for approximately one-third of cases of tumor-associated polycythemias. The tumor tissue has been demonstrated to produce excessive amounts of EPO, and the erythrocytosis resolves with surgical resections of the tumor. The mechanisms underlying the activation of the EPO gene have been related to somatic mutation of the VHL gene in clear cell renal carcinomas. Clear cell carcinoma is associated with erythrocytosis and high serum EPO levels caused by increased expression of EPO mRNA, HIF-1α, and HIF-2α.[8] These abnormalities were related to

a point mutation in the VHL gene that impaired the bindings of HIF-1α to VHL, leading to its accumulation and increased production of EPO. Polycythemia is also a well-described paraneoplastic manifestation of hepatocellular carcinoma in 2.5% to 10% of patients and is again caused by the production of EPO by the tumor. Polycythemia in hepatoma patients is strongly related to tumor burden and elevated α-fetoprotein levels. Polycythemia has also been associated with cerebellar hemangioblastomas and very large uterine fibromas. In tumor-associated erythrocytosis, EPO production has been shown to be autonomous of hypoxic stimuli. Paragangliomas are tumors arising from extra-adrenal paragangliar neural crest cells. Most paragangliomas arise retroperitoneally or within the peritoneal cavity and are associated with high EPO levels and erythrocytosis. After tumor resection, reduction of the EPO levels and erythrocytosis occurs. Germ line mutations involving two Krebs cycle enzymes, fumarate hydratase and succinate dehydrogenase, have been implicated in the hereditary paraganglioma–pheochromocytoma syndrome. In tumors deficient in these enzymes, fumarate and succinate accumulate, which inhibits PHD, leading to accumulation of HIF-1α and eventually resulting in erythrocytosis. In another patient with a paraganglioma who did not have the inherited syndrome but had extreme erythrocytosis, a mutation in PHD2 was demonstrated in germ line cells. In this patient's tumor, tumor analysis showed LOH with the mutant allele predominating, which was associated with a loss of function. The degradation of both HIF-1α and HIF-2α was increased. These data indicate that PHD2 can act as a tumor suppressor gene. The tumor suppressor activity of PHD2 has also been reported in sporadic endometrial, breast, and pancreatic cancers with inactivating mutations ultimately leading to the increased production of growth factors that contribute to tumor growth.

Polycythemia in Endocrine Disorders

Polycythemia is also associated with Cushing syndrome, acromegaly, and primary aldosteronism. Secondary polycythemia can also be seen in 24% of older hypogonadal men receiving long-term androgen replacement therapy and a significant number of competitive athletes taking anabolic steroids. For instance, in a small study of professional bodybuilders, 67% of those examined had hematocrit levels above 50%. The effectiveness of drug screening in athletic competitions is demonstrated by the very low rate of positive test results for androgens (<2% of 170,000 tests) on random testing at the Olympic Games and other international events. Despite previous assertions regarding increased EPO excretion after androgen therapy, none of the athletes examined had elevated levels of EPO. Recombinant human EPO has also been abused by athletes competing in endurance sports and can be detected by analyzing the individual's hematocrit level, reticulocyte count, percentage of macrocytic RBCs, serum EPO level, serum transferrin receptor level, and electrophoretic mobility of the EPO molecule (recombinant EPO is less negatively charged than endogenous EPO).

Congenital Secondary Polycythemias

High-Oxygen-Affinity Hemoglobins and Bisphosphoglycerate Deficiency

More than 100 mutations of hemoglobin lead to increased oxygen affinity and thus decreased oxygen delivery and compensatory polycythemia (see Chapter 41). These mutations involve either the α- or β-chain globin chains. Such polycythemias are usually well tolerated in young patients but may lead to thrombotic complications in older patients. High-oxygen-affinity hemoglobin variants are transmitted as autosomal dominants. Phlebotomy therapy of such patients has been reported to be of no beneficial value and has been shown to decrease exercise tolerance and anaerobic threshold. The best test to detect a high-oxygen-affinity hemoglobin relies on the determination of hemoglobin dissociation kinetics and P50 (partial pressure of O_2 at which hemoglobin is 50% oxygenated). If cooximetry is not available, the P50 can be mathematically estimated from a venous blood gas measurement by using a computer algorithm, which is available online.

Whereas a $P_{50}O_2$ below 17 mm Hg is indicative of a mutant hemoglobin with high oxygen affinity, a level above 35 mm Hg is strongly suggestive of a mutant hemoglobin with a low oxygen affinity. Hemoglobin electrophoresis is not a reliable screen to rule out hemoglobin mutations because only about half of these mutants are electrophoretically distinguishable. A hemoglobin electrophoresis will reveal the presence of an abnormal hemoglobin only if the mutation leads to a change in electrical charge. In 30 hemoglobin variants, such a charge differential was not present, and high-performance liquid chromatography or mass spectrometry followed by polymerase chain reaction (PCR)–directed sequencing was required to make the diagnosis.

A rare cause of congenital polycythemia is 2,3-BPG (previously known as 2,3-DPG) deficiency (see Chapter 42). 2,3-BPG is synthesized in RBCs and binds to hemoglobin, thereby reducing its affinity for oxygen. An absence of 2,3-BPG therefore leads to increased affinity of hemoglobin for oxygen, resulting in a lifelong hypoxic stimulus and erythrocytosis.

Congenital methemoglobinemias, whether caused by cytochrome b5 reductase mutations or globin mutations, may be associated with mild polycythemia (see Chapter 41). When hemoglobin is oxidized to methemoglobin, all of the four subunits of the tetramer may be affected, eliminating the oxygen transport capacity of hemoglobin.

Hypoxia Inducible Factor Pathway Mutations Leading to Erythrocytosis

Alterations of a number of proteins in the HIF pathway have been shown to lead to increased EPO production and erythrocytosis (see Fig. 67-1).[9] Chuvash polycythemia (CP) is an autosomal recessive disorder associated with germline mutations of VHL and erythrocytosis. CP was first described in the mid-1970s and is endemic in the Chuvash population of the Russian republic. The serum EPO concentration in affected individuals is elevated compared with healthy first-degree family members, although some patients may have normal serum EPO levels. They also have elevated levels of VEGF and plasminogen activator inhibitor-1. The erythroid progenitors of patients with CP are also hypersensitive to EPO; thus CP has characteristics of both primary and secondary polycythemias. A homozygous missense mutation in the VHL gene, VHL598C→T mutation, has been identified in CP patients. The disorder is characterized by high hemoglobin levels (usually >20 g/L), increased plasma EPO levels, varicose veins, vertebral hemangiomas, low blood pressure, and an elevated concentration of VEGF. The defective VHL gene product is not capable of promoting the ubiquitin-mediated degradation of HIF-1α and HIF-2α, thereby leading to increased levels of both of these proteins and increased elaboration of EPO. Inheritance occurs as an autosomal recessive, and the frequency of the allele has been estimated to be at 0.057 in the Chuvash population. Several other similar types of mutations in VHL have been described that have been observed in a variety of other ethnic groups. A number of heterozygotes with erythrocytosis have been reported, which can likely be accounted for by an as yet undiscovered additional defect. CP is associated with a high mortality rate from thrombotic and hemorrhagic vascular complications. Cerebrovascular events are especially common causes of death. The median age of death from cerebrovascular events is 42 years. Estimated survival to age 65 years is 29% for individuals with CP and 64% for age-matched community members. There is a perfect genotype–phenotypic correlation, with all patients with CP being homozygotes for the mutation. Interestingly, heterozygous carriers do not develop erythrocytosis but do have lower blood pressures and do not seem to be at increased risk for tumors, which contrasts with patients with VHL syndrome. Patients with CP also have larger livers, spleens, and kidneys than control patients, which has been attributed to enhanced cellular proliferation caused by HIF-2α suppression of p21Cip1.

Germline mutations of VHL alleles have been reported in several patients with apparent congenital polycythemia that had no evidence of developing a tumor; some of these subjects had germline mutations of both VHL alleles. Other subjects with congenital polycythemia of various ethnicities, including Pakistanis, Punjabis, African Americans, and whites, harboring homozygosity for the CP VHL mutation or double heterozygosity for CP and other VHL mutations, have been found. The VHL598C→T mutation has been shown to originate in a single haplotype in the Chuvash patients, as well as in whites, Asian Indians, and one African American individual. Homozygosity of this mutation appears to be the most common genetic defect leading to congenital polycythemia. The mutation originated from a single founder 12,000 to 51,000 years ago. This suggests that such wide dissemination from the original founder may be associated with some survival advantage for heterozygotes carrying this mutation. Such an advantage might be related to a subtle improvement of iron metabolism, erythropoiesis, embryonic development, energy metabolism, or some other yet unknown effect.

von Hippel-Lindau mutations are likely the most common cause of congenital polycythemias, greatly exceeding the number of patients with hemoglobin chain mutations. In point of fact, in one study of more than 200 unrelated subjects with apparently congenital polycythemia, none had a 2,3-BPG deficiency, two had a globin mutation (Hgb Vanderbilt, and Hemoglobin San Diego), and 12 had EPOR mutations to account for their polycythemia. By contrast, when 50 patients were examined for the VHL mutation, 22 had VHL mutations, most of them being the CP VHL mutation, occurring either homozygously or in combination with another VHL mutation. The failure of patients with CP to develop VHL syndrome tumors is consistent with the concept that deregulation of H1F-1α and VEGF are not sufficient to cause tumors. A cluster of patients with clinical features identical to patients with CP has been documented on the island of Ischia in the Bay of Naples, Italy. All of these patients also had the VHL598C→T mutation. Twelve of the 14 patients were homozygotes, and two were heterozygotes. The homozygotes had symptoms identical to patients in Chuvashia with this mutation. Unlike heterozygotes in Chuvashia, the heterozygotes from Ischia developed erythrocytosis associated with high EPO levels, which raises the possibility that genetic alterations of additional components of the oxygen-sensing pathway other than VHL may contribute to the development of erythrocytosis in the Italian patients. The disorder in Ischia has a gene frequency even higher than that in Chuvashia, with 14% of the population estimated to be heterozygotes, which has led to the suggestion that heterozygotes have a survival advantage, perhaps caused by heterozygosity conferring protection from developing anemia.

The Chuvash mutation has also been shown to have a profound effect on the cardiopulmonary system. Patients with CP have significant abnormalities of cardiopulmonary physiology, including elevated basal ventilation rates and increased pulmonary vascular tone, with extremely high ventilatory rates and heightened pulmonary vasoconstriction and heart rates in response to acute hypoxia. These observations indicate that the VHL–HIF pathway might also play a central role in calibrating the pulmonary system to hypoxic challenges. Such undesirable exaggerated hypoxic responses and the resulting elevated pulmonary vascular hypertension may contribute to the morbidity and mortality associated with CP. Increased expression of endothelin-1 has been documented in patients with CP. Endothelin-1 has been associated with the development of hypoxia-related pulmonary hypertension. Endothelin-1 receptor inhibitors might therefore be useful in reversing the associated pulmonary hypertension in these patients. Treatment strategies for patients with CP have included phlebotomy, aspirin, and occasionally chemotherapy. It is unknown whether such therapeutic strategies alter the natural history of this disorder. A variety of HIF-1 inhibitors being currently evaluated for the treatment of tumor patients might potentially also be useful for the treatment of patients with CP.

Recently, the CP-VHL mutants have been shown to affect EPO signaling in erythroid progenitor cells of patients with CP. JAK2 phosphorylation of STAT5 triggers not only erythroid progenitor development but also a negative feedback mechanism by transactivating the expression of SOCS family members which bind and inhibit activated JAKs by promoting their ubiquination and protosomal degradation. The CP mutation causes conformational changes leading to a tight CP–VHL–SOCS1 association, thereby slowing phosphorylated JAK2 degradation. These events lead to hyperactivation of the JAK2–STAT pathway in erythroid progenitor cells causing their hypersensitivity to EPO, which likely contributes to the excessive erythrocytosis characteristic of CP.

Additional genetic abnormalities of oxygen sensing have been reported that lead to familial polycythemia. A heterozygous C-to-G change at base 950 of the coding sequence of PHD2 (P317R mutation) was first detected in all three affected family members with this syndrome. Hydroxylation of HIF-1 by PHD2 facilitates its interaction with VHL, thereby favoring its ubiquitination and degradation by the proteosome.[10] The failure of PHD2 P317R to bind the HIF-1 and HIF-2α and promote HIF hydroxylase activity ultimately leads to increased HIF-l and EPO levels, resulting in the development of erythrocytosis. The PHD2 P317R mutation is inherited as an autosomal dominant trait in contrast to the CP defect, which is an autosomal recessive disorder. Polycythemic patients with PHD2 P317R do not have any evidence of tumors characteristic of the VHL syndrome. Additional mutations in PHD2 have been reported that lead to erythrocytosis. All of these mutations are germline and heterozygous encoding predicted mutant full-length PHD2 proteins. Two of these patients with PHD mutations also have an exon 12 JAK2 mutation that is associated with PV. The interaction between these two defects requires further study.

A series of HIF-2α gain of function mutations have also been reported to lead to familial erythrocytosis.[9] These mutations lead to weakened bonds between PHD2 and HIF-1α, resulting in less hydroxylation of HIF-1α and subsequent recognition of HIF-1α by VHL. Many of these patients present in their twenties, although patients have also been diagnosed in their fifties with erythrocytosis associated with high EPO levels. All patients have heterozygous mutations, suggesting that one allele is sufficient to cause erythrocytosis. It is not unusual for patients to have a clinical history of thrombotic disorders, but there does not appear to be an increased incidence of cancer.

Neonatal Polycythemia

Because of the high oxygen affinity of fetal hemoglobin, many neonates have markedly elevated hematocrit levels. Babies with hematocrit levels over 65% have more neurologic and functional impairments and are more likely to be born to diabetic mothers. Although phlebotomy has been recommended, there is little evidence that it has been beneficial for these babies.

Drug-Induced Erythrocytosis

The administration of EPO, corticosteroids, or androgens to an excessive degree has each been associated with reversible erythrocytosis. Androgens have been shown to simulate EPO production and to directly affect erythroid progenitor cells. Approximately 5% of patients receiving long-term testosterone therapy for testosterone deficiency syndrome develop erythrocytosis. Androgens activate HIF-1 and HIF-1-regulated gene expression, leading to increased expression of VEGF and presumably EPO. Rarely, erythrocytosis can be the presenting manifestation of Cushing syndrome. Blood doping refers to the use of EPO to increase the RBC mass and enhance oxygen delivery with the hope of increasing endurance performance in athletes. A monitoring of an athlete's hematologic profile longitudinally provides some insight into the likelihood of blood doping playing a role in the development of erythrocytosis

The development of paradoxical polycythemia in three patients with VHL syndrome and central nervous system or retinal hemangioblastomas treated with the VEGF receptor inhibitor SU5416 is surprising but has been reported. The cause of these phenomena

remains unknown. In addition, reversible erythrocytosis has been reported with the use of the tyrosine kinase inhibitors sunitinib and sorafenib in over 20% of patients with a variety of metastatic malignancies including renal cell carcinoma, hepatomas, and melanomas. The erythrocytosis associated with these drugs is not associated with further elevation of EPO levels but has been suggested to be a consequence of sensitization of erythroid cells to EPO.

POLYCYTHEMIA VERA

Polycythemia vera is a clonal, chronic, progressive myeloproliferative neoplasm (MPN) often of insidious onset characterized by an absolute increase in RBC mass and also usually by leukocytosis, thrombocytosis, and splenomegaly. PV leads to excessive proliferation of erythroid, myeloid, and megakaryocytic elements within the BM. Vaquez first described this clinical entity in 1892, noting the characteristic physical findings. At the turn of this century, Cabot and Osler independently associated the name PV with this clinical disorder.

Polycythemia vera differs from many other hematologic malignancies in that prolonged survival is enjoyed by most patients if the excessive production of RBCs and platelets can be controlled. This prolonged survival, however, can be punctuated by the development of other syndromes, such as myelofibrosis (MF), termed post-PV MF, and acute leukemia (Fig. 67-3). Frequently, patients present asymptomatically to a physician only to find that they have splenomegaly, isolated erythrocytosis, or thrombocytosis. Left untreated, these patients will become symptomatic, owing to the excessive production of RBCs, platelets, or both, leading to arterial or venous thromboses, aquagenic pruritus, and symptoms caused by increasing splenomegaly. After a number of years, the erythrocytotic phase of the disease frequently becomes inactive, and the patient may no longer have the sequelae of excessive RBC production. Subsequently, these patients can develop post-PV MF, which is frequently indistinguishable from another MPN, primary MF (PMF). Finally, a significant proportion of these patients will go on to develop acute myeloid leukemia (AML). Only a limited number of patients undergo this orderly transition; many patients transition from the polycythemic phase directly into an acute leukemia or a myelodysplastic disorder.

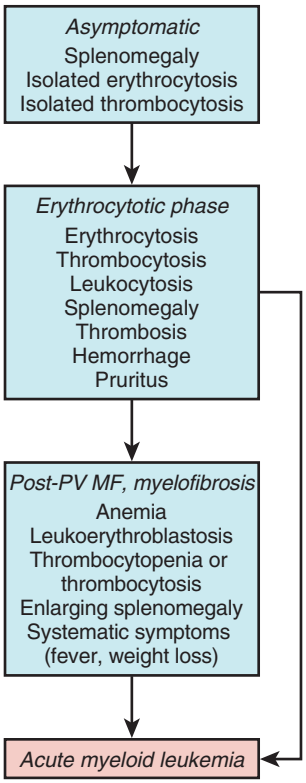

Figure 67-3 EVOLUTION OF POLYCYTHEMIA VERA (PV). *MF,* Myelofibrosis.

The transition from one phase of this MPN to another is not necessarily unidirectional. A number of cases of presumed PMF have been described in which chemotherapy treatment has resulted in a striking decrease in BM fibrosis associated with the development of erythrocytosis and a syndrome that is virtually indistinguishable from de novo PV. The constantly changing clinical picture of this malignant hematologic disorder requires careful observation and treatment to deal with the numerous problems that can be encountered.

EPIDEMIOLOGY

Polycythemia vera is the most common primary polycythemia. Reported incidence rates are around 2.8 per 100,000 persons per year. It is important to emphasize that no or very few population-based estimates of the prevalence of this disorder are presently available. Actual determination of its prevalence has been a difficult process because of the need in the past to pursue an extensive diagnostic evaluation to differentiate this disorder from other causes of spurious or absolute erythrocytosis. The diagnosis of PV has been simplified by the identification of PV-associated mutations (JAK2V617F and JAK2 exon 12 mutations), permitting for the first time molecular epidemiologic studies. The prevalence of the JAK2V617F mutation in a normal population in Denmark was recently determined to be 0.2%, with 63% of these individuals not having a previously detected hematological malignancy.[11] The presence of the mutation was associated with increasing age, male sex, and a lower cumulative survival. Several groups have reported that 50% of patients with a splanchnic vein thrombosis without an overt MPN are JAK2V617F positive and that more than 50% of these individuals subsequently develop an MPN. However, the incidence of the mutation with unprovoked thromboembolism in the more usual sites (deep venous thrombosis involving the leg veins or pulmonary embolism) ranges between 0.2 and 1.0%. Such data have led to the conclusion that systematic screening for JAK2V617 in such a patient population is not warranted.

The prevalence of PV has been reported by several investigators to be higher among American Jews and lower among African Americans. The reported lower incidence in African Americans might reflect a referral bias characteristic of centers with research interest in MPN because the authors, when practicing in several large urban areas, have observed a considerable number of African Americans with MPNs, including PV. The incidence of the disorder is greater among Ashkenazi Jews, who originate from eastern and central Europe, than among Arabs and Sephardic Jews. Interestingly, extremely low occurrence rates have been reported from Japan. These findings suggest that important genetic factors might be involved in the biogenesis of this disorder. The importance of genetic factors in the origin of this disease is further emphasized by reports of multiple cases of JAK2V617F or JAK2 exon 12 mutation–positive and –negative MPN, including PV, within multiple generations of a number of families. These forms of familial PV must be distinguished from PFCP, CP, and polycythemia associated with mutations in the HIF pathway. The reports of families in which multiple members have PV first raised the possibility that a genetic predisposition to acquire such mutations exists in these families that is inherited in an autosomal dominant pattern with decreased penetrance. Clinical analyses of affected family members confirmed that they have clonal hematopoiesis and that their clinical manifestations are identical to patients with sporadic PV. In a large population study recently reported from Sweden, the relatives of MPN patients were shown to have a significantly increased risk of developing a Philadelphia chromosome–negative MPN and possibly chronic myeloid leukemia.[12] It was estimated that first-degree relatives of MPN patients have a five- to sevenfold greater risk of developing an MPN, again supporting the hypothesis that common strong susceptibility genes predispose one to develop PV, essential thrombocytosis (ET), PMF, and possibly CML.

One notable exception to the low prevalence of PV in Japan has been the higher incidence observed among populations exposed to atomic bomb explosions. The possibility that radiation exposure is an etiologic factor in the generation of PV was also raised by the observation in the United States of four cases of PV 10 to 20 years after a nuclear explosion in which 3000 military observers were exposed. An epidemiologic investigation that focused on occupational exposure among petroleum refinery and chemical plant workers has revealed an increased incidence of PV relative to the general population. In this study, the increased incidence of PV was linked to similar increases in the frequency of multiple myeloma and non-Hodgkin lymphoma, suggesting involvement of a putative environmental toxin that may have broad hematopoietic toxicity. The possibility of environmental factors contributing to the development of PV was recently raised by the identification of a cluster of patients with JAK2V617F-positive PV in an area of Eastern Pennsylvania that contained numerous sources of hazardous materials including, waste coal power plants and U.S. Environmental Protection Agency Superfund sites. What possible environmental factors might contribute to this fourfold increase in the number of PV cases is currently the subject of intense investigation.

Slightly more men than women develop PV, the male-to-female ratio being approximately 1.2 to 1. The average age at diagnosis is 60 years, but the disease is observed not infrequently in female patients younger than 30 years of age. In several large studies, 5% of patients with PV were younger than 40 years of age, 1% were younger than 25 years at diagnosis, and 0.1% were younger than 20 years. Small numbers of patients with PV have been reported who presented during childhood. More importantly, in several of these children, hepatic vein thrombosis (Budd-Chiari syndrome) was the initial manifestation of the disease. In fact, a 7-month-old infant with PV and an acquired somatic JAK2V617F mutation that likely occurred in utero has been reported.

Pathobiology

Considerable speculation has centered on the pathobiology of the erythrocytosis that characterizes PV. The expanded RBC mass in PV patients is due to a two- to threefold increase in the production of RBCs by a hyperplastic BM and is not attributable to prolongation of the RBC lifespan. Granulocyte and platelet production is also increased in this disorder. This overly exuberant production of all cellular elements of the blood suggests that the basic defect resides at the level of the hematopoietic cellular hierarchy from which each of these cells originates, the pluripotent hematopoietic stem cell (HSC).

A variety of studies have documented serum EPO levels in patients with PV, secondary erythrocytosis, and relative polycythemia in normal adults. Serum EPO levels have been shown to be subnormal in patients with PV, elevated in many but not all cases of secondary erythrocytosis, and normal in patients with relative polycythemia, indicating that PV cannot be an abnormality of EPO production.

In 1951, Dameshek postulated that chronic myeloid leukemia, PV, essential thrombocythemia, and PMF were related disorders, which he called MPD, but are now termed MPNs because of the evidence that these disorders are hematologic malignancies.

Since the mid-1970s, data have accumulated that conclusively demonstrate PV to be the result of a neoplastic proliferation of hematopoietic cells. The cellular origin of the disorder was first established by the analysis of glucose-6-phosphate dehydrogenase (G6PD) isoenzymes in African American women who were heterozygous for this X-linked gene. This approach was based on the random irreversible inactivation of one X chromosome in each female somatic cell during embryogenesis. Inactivation of the same X chromosome occurs in the progeny of these cells. A normal African American female heterozygous for G6PD will therefore have approximately equal populations of BM cells with a different G6PD isoenzyme. The G6PD isoenzymes can be readily distinguished by electrophoretic methods.

This approach was exploited in a seminal study by Adamson and coworkers in an effort to determine the cellular origin of PV. They presumed that cells composing a tumor that arises from a single cell in a G6PD heterozygote would express a single isoenzyme type, but a neoplasm originating from multiple cells would express both isoenzyme types. These investigators found that circulating RBCs, granulocytes, and platelets obtained from African American female patients who were G6PD heterozygotes express the same isoenzyme, but skin and cultured BM fibroblasts obtained from these same patients demonstrate both isoenzymes. They concluded that PV represented a clonal proliferation of neoplastic HSCs and was not multicellular in origin or the consequence of excessive proliferation of normal HSCs.

The clonality of blood cell production in PV has subsequently been confirmed using restriction fragment length polymorphisms of the active X chromosome. A monoclonal pattern of X chromosome inactivation has been defined in RBCs, granulocytes, monocytes, and platelets in female patients with PV.

On the basis of the knowledge that RBC production in PV is not associated with excessive EPO production, numerous investigators hypothesized that the erythroid progenitor cell in this disorder is no longer subject to physiologic regulators. PV BM can form substantial numbers of erythroid colonies in vitro in the absence of exogenous EPO, but normal human BM is incapable of forming such colonies without the addition of EPO. These erythroid colonies were termed *endogenous colonies*. When erythroid PV and normal BM were subsequently assayed in the presence of EPO, PV BM was characterized by a higher cloning efficiency. Additional observations suggested that the altered response to cytokines was not restricted to EPO but included a variety of other cytokines and that this cytokine hypersensitivity was characteristic of progenitor cells committed to a variety of other lineages.

In addition, BM cells cloned from African American female G6PD heterozygotes with PV in the presence and absence of exogenous EPO revealed that the erythroid colonies that formed in the absence of exogenous EPO contained the same G6PD isoenzyme type as that expressed by peripheral blood elements. Thus the so-called endogenous erythroid colonies arose from the abnormal clone that was responsible for supplying RBCs, granulocytes, and platelets to the peripheral blood. When exogenous EPO was added, increasing numbers of colonies were formed containing cellular elements expressing the other G6PD isoenzymes; presumably, these colonies originated from cells not involved in the malignant process. Similarly, small numbers of granulocyte–macrophage colonies not originating from the PV clone were also observed in these assays. These data collectively indicate the existence of malignant and nonmalignant populations of HPCs in PV BM. The relative frequency of the neoplastic clone in relation to normal progenitor cells was further examined by Adamson and coworkers, who, by monitoring the proportion of neoplastic erythroid clones and their numeric relationship to normal clones over a period of several years, showed disease progression to be associated with a significant decline in the frequency of normal progenitor cells and increasing proportion of the neoplastic clone. Erythroid progenitor cells from PV patients are, in fact, abnormally sensitive to the actions of this EPO. This increased responsiveness allows these cells to form colonies in the presence of small amounts of EPO. Most PV patients possess two distinct populations of erythroid progenitor cells: a normally EPO-responsive population and a population of cells similar in proliferative and maturational behavior in vitro but requiring little or no EPO. These investigators suggested that the proliferation of the normal progenitor cells in vivo was at a disadvantage.

A number of investigators have demonstrated that the increased responsiveness of these BM progenitor populations extends to their responses to other cytokines, including SCF, IL-3, GM-CSF, and IGF-1. These studies also demonstrated that BM fractions enriched for granulocyte–macrophage progenitors as well as megakaryocyte progenitors from the patients had a heightened responsiveness to IL-3 and GM-CSF. The dogma that the hyperresponsivity of PV progenitor cells to a variety of growth factors (EPO, IL-3, GM-CSF, steel factor) is the underlying defect that leads to PV has been universally accepted.

Many investigators have examined the possibility that the hematopoietic defect in PV could be accounted for by genetic alteration of cytokine receptors expressed by affected hematopoietic cells. In PV, the EPOR is structurally similar to the normal EPOR, and mutations in the EPOR are not directly involved in the pathobiology of PV. Furthermore, no significant differences in the number, dissociation constant, or internalization rate of receptors for steel factor have been detected in the erythroid progenitor cells of PV patients.

Identification of JAK2V617F Mutation in PV

For more than 2 decades, a number of research groups have been searching for the genetic defect underlying PV. Most groups predicted that this defect involved the signaling pathways downstream of the EPOR. These pathways include the tyrosine kinase JAK2 and the transcriptional signal transducers and activators of transcription STAT3 and STAT5. The initial discovery of a mutation was predicated on a somewhat simplistic yet revealing set of experiments performed by Vainchenker and colleagues in France and reported in 2005.[13] They observed that the inhibition of JAK2 by a small molecule (AG490) or by small interfering RNA (siRNA) reduced EPO-independent colony formation by PV BM mononuclear cells. This observation prompted them to directly sequence JAK2 in the hematopoietic cells of PV patients and to discover a single recurrent point mutation. A guanine-to-thymine mutation was observed that resulted in a substitution of valine to phenylalanine at codon 617 within the pseudokinase domain (JH2) of JAK2 (JAK2V617F) (Fig. 67-4). These findings were quickly confirmed by several different groups. Kralovics et al[14] had previously identified a region of LOH on chromosome 9p in PV and identified a 6·2-Mbp region common to all PV patients screened. Because this region contained JAK2, with its known role in erythropoiesis, it was screened for mutations and the same JAK2V617F mutation identified. Three other groups targeted JAK2 as part of a global sequencing screen of tyrosine kinases and phosphatases in MPDs. Analysis of germline DNA demonstrated that JAK2V617F is an acquired somatic mutation present exclusively in hematopoietic cells. All patients with PV have a population of erythroid progenitor cells that are homozygous for the mutation. Using quantitative PCR, patients can be divided into those with a low allele

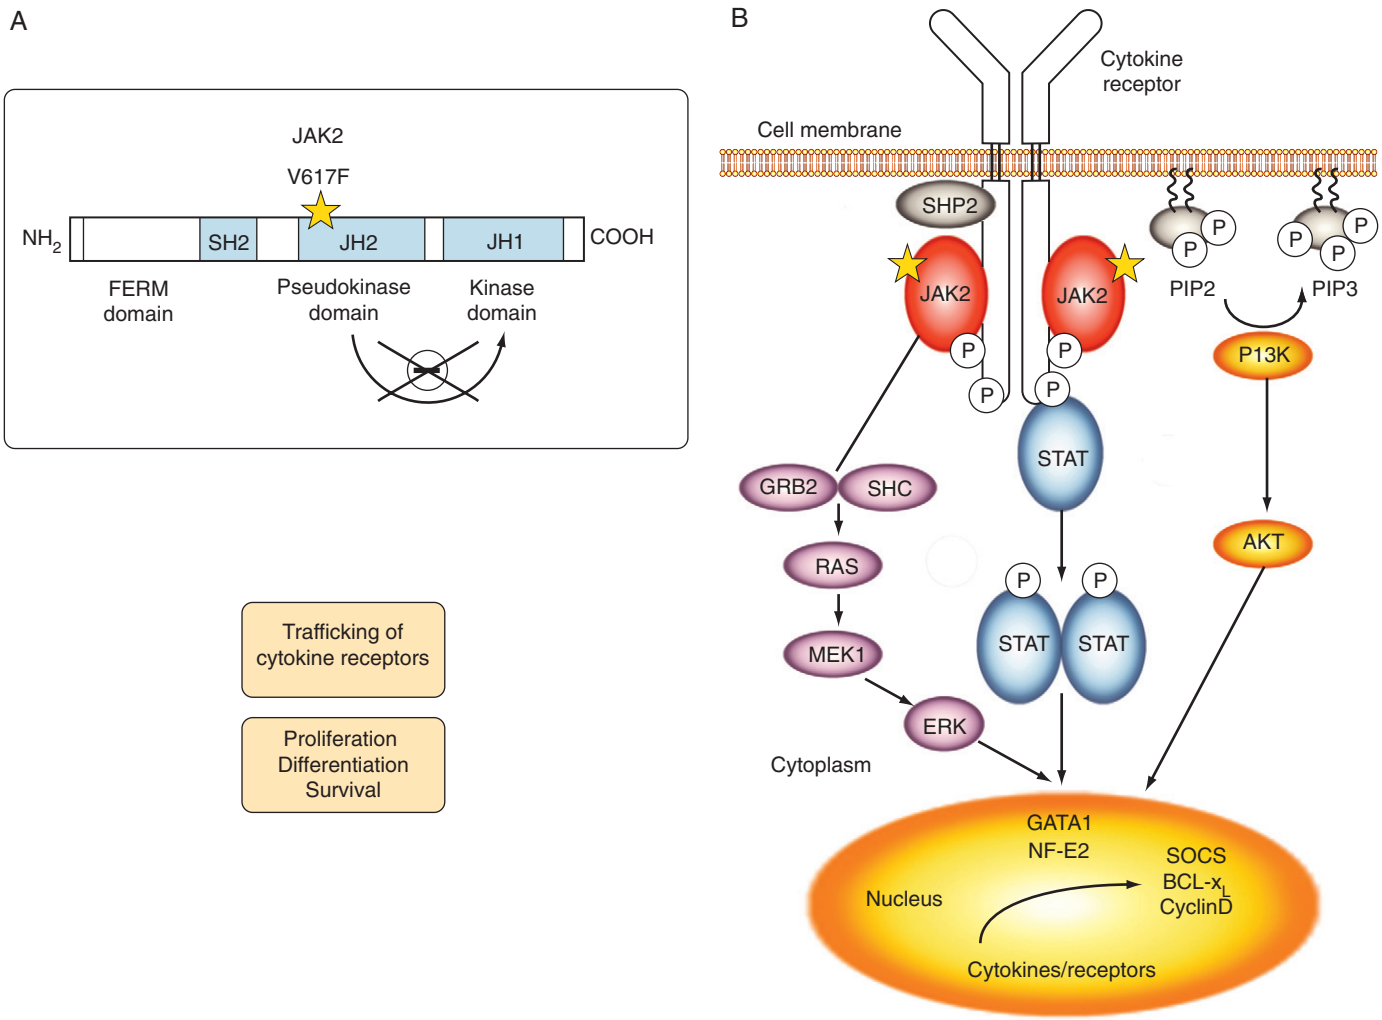

Figure 67-4 JAK2V617F SIGNALING IN MYELOPROLIFERATIVE DISORDERS. **A,** Structure of JAK2V617F: the mutation is located in pseudokinase Janus kinase (JAK) homology domain 2 (JH2) and disrupts the autoinhibition of this regulatory domain. Consequently, the tyrosine kinase corresponding to the JH1 domain is constitutively activated. **B,** In the presence of a homodimeric cytokine receptor (e.g., erythropoietin receptor [EPOR]), the two JAK2V617F proteins bound to the intracellular domain of the receptor transphosphorylate its tyrosine residues. In turn, STAT5 (signal transducer and activator of transcription 5), phosphatidylinositol 3-kinase (PI3K), and renin–angiotensin system (RAS) signaling pathways are activated, leading to the downstream modulation of transcription and protein levels for cell cycle, proliferation, and apoptosis-related factors. *Bcl-X_L,* B cell lymphoma-extra large; *ERK,* extracellular signal-related kinase; *GATA,* GATA-binding factor; *GRB,* growth factor receptor-bound protein; *MEK1,* dual specificity mitogen-activated protein kinase kinase 1; *NF,* nuclear factor; *P,* Phosphate; PIP2 and PIP3, phosphatidyl inositol bi- and triphosphate; *SH2,* src homology 2; *SOCS,* suppressor of cytokine signaling. *(From Delhommeau F, Pisani DF, James C, et al: Oncogenic mechanisms in myeloproliferative disorders.* Cell Mol Life Sci *6363:2939, 2006.)*

burden of JAK2V617F in granulocytes ha (<50%) and patients with a higher burden of JAK2V617F (>50%). A subset of patients with PV are homozygous for JAK2V617F, which was demonstrated to be the result of mitotic recombination and duplication of the mutant allele (Fig. 67-5). The occurrence of this mitotic recombination event has been observed during the clinical course of individual patients, leading to JAK2V617F heterozygote patients becoming homozygotes over time. The concept of the conversion of JAK2V617F low burden to high burden is further supported by the observation that the median duration of disease at the time of evaluation was 48 months in high-burden PV patients as compared with 23 months in low-burden PV. These observations are consistent with a multistep pathogenesis of PV. The first step consists of the acquisition of JAK2V617F, which results in a low allele burden of JAK2V617F, followed by a second step, homologous recombination, that leads to JAK2V617F homozygous progenitor cells and eventually granulocytes with a high burden of JAK2V617F. It remains unknown at present if a lesion occurring before acquisition of the JAK2V617F mutation predisposes an individual to acquire JAK2V617F.

A number of groups have reported the frequency of JAK2V617F in patients with MPNs (see Table 67-2). The mutational frequency of JAKV617F in PV is greater than 95% of cases. Approximately 50% to 60% of patients with ET and PMF are also *JAK2V617F* positive. ET is distinguished from PV by being associated with a low allele burden. In the overwhelming majority of cases, PV is characterized by a population of JAK2V617F homozygous colonies with some heterozygous and wild-type colonies. By contrast in ET, there are few homozygous colonies, with the majority being heterozygous or wild type. The majority of ET and PMF patients who are negative for *JAK2V617F* have clonal hematopoiesis, which indicates that these JAK2V617F diseases likely are the consequences of other genetic events, several of which have recently been described and are discussed in Chapter 69. The *JAK2V617F* allele has also been observed in a limited number of patients with chronic myelomonocytic leukemia, myelodysplastic syndromes (MDS), refractory anemia with ringed sideroblasts and thrombocytosis, and AML, although most *JAK2V617F* mutations in AML occur in patients with a preceding diagnosis of PV, ET, or PMF. JAK2V617F is an acquired somatic mutation, does not appear in nonhematopoietic cells, and has not been detected in patients with secondary erythrocytosis. Moreover, JAK2V617F has not been observed in lymphoid malignancies, although other mutations in *JAK2* have been identified in 10% of patients with pediatric high-risk ALL.

Other JAK2 Mutations in Polycythemia Vera

Other mutations of JAK2 associated with erythrocytosis, however, can also constitutively activate JAK2 kinase activity. Several gain-of-function mutations affecting JAK2 exon 12 within an area immediately adjacent to pseudokinase domain of JAK2V617F-negative patients have been identified in 2.5% to 3.4% of PV patients and approximately 30% of JAK2V617F-negative PV. To date, 17 different such mutations have been identified.[14] Two-thirds of patients with a JAK2 exon 12 mutation presented with an isolated erythrocytosis and distinctive BM morphology and had reduced serum EPO levels, but the remainder of patients have erythrocytosis plus leukocytosis, thrombocytosis, or both. These exon 12 mutations perturb the autoinhibitory domain of JAK2. JAK2 exon 12 mutations have not been reported in patients with ET or PMF but have been occasionally observed in patients with refractory anemia and ringed sideroblasts associated with thrombocytosis. Erythroid colonies cloned from their blood samples in the absence of exogenous EPO were most frequently heterozygous for the mutation, with homozygous colonies only rarely occurring, but colonies homozygous for the mutation occur in most PV patients with JAK2V617F, suggesting that a JAK2 exon 12 mutation results in a stronger activation of the JAK2-mediated intracellular signaling pathways. Patients with exon 12 mutations can develop

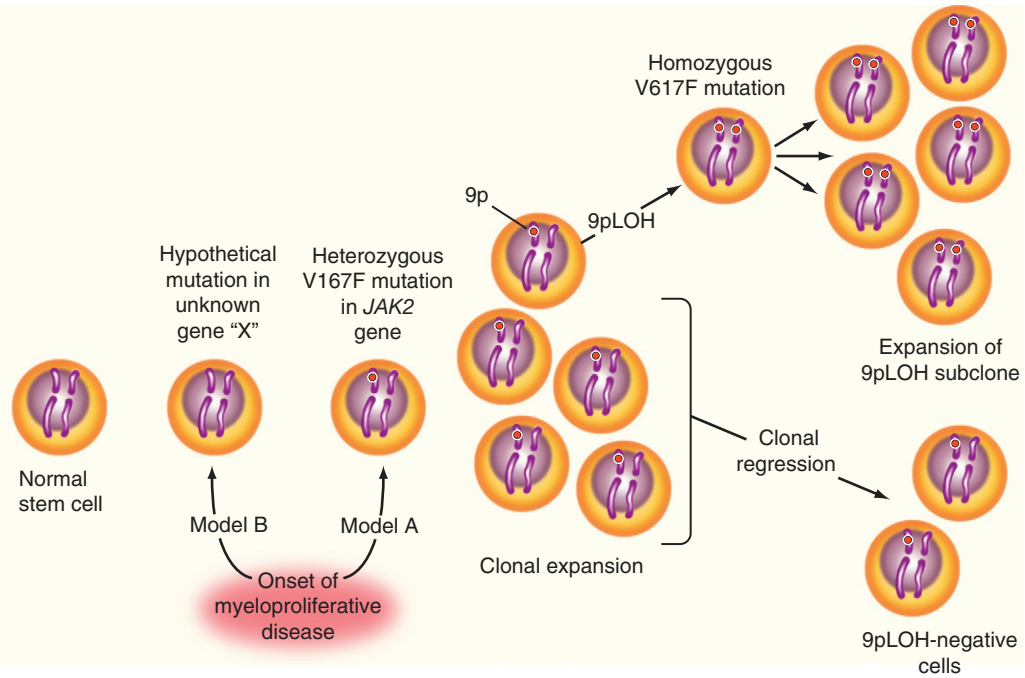

Figure 67-5 POSSIBLE ROLE OF JAK2V617F IN THE BIOLOGY OF MYELOPROLIFERATIVE DISORDERS. The chromosome 9 with the wild-type *JAK2* sequence (G) is depicted in *white,* and the chromosome 9 with the G-T transversion (T) is shown in *red*. *Circles* symbolize the nuclei of the cells. Deletion of the telomeric part of wild-type chromosome 9p as a potential mechanism for 9pLOH is shown on the *left*. Alternatively, mitotic recombination could also result in 9pLOH, shown on the *right*. The events during mitosis and the resulting cell progeny after mitotic recombination of chromosome 9p are also shown. *(Adapted from Kralovics R, Passamonti F, Buser AS, et al: A gain-of-function mutation of JAK2 in myeloproliferative disorders.* N Engl J Med *352:1779, 2005.)*

thrombotic episodes and can evolve into post-PVMF or acute leukemia. BaF3 cells expressing the murine EPOR and carrying exon 12 mutations can proliferate without added IL-3. They also exhibited increased phosphorylation of JAK2 and extracellular signal-related kinase (ERKs) as compared with cells transduced by wild-type JAK2 or JAK2V617F. This mutation resulted in a myeloproliferative disorder phenotype, including erythrocytosis, in retroviral murine BM transplantation model. JAK2 exon 12 mutations, therefore, might define a distinctive MPN that affects patients who had previously been carrying a diagnosis of IE. In several series, approximately 2.7% of patients with a clinical syndrome that resembles PV have been observed who have a wild-type JAK2. The existence of such patients may be the result of several factors, including limited sensitivity of the assay used for genotyping; prior treatment with interferon (INF), which might eliminate the JAK2 mutations; or lack of efforts to exclude inherited genetic disorders associated with erythrocytosis that have been described in this chapter. Alternatively, additional acquired genetic lesions that have yet to be described may be responsible for the disease phenotype.

JAK2V617F Is Likely Not the Disease-Initiating Event in Polycythemia Vera

Despite data generated using a variety of mouse models suggesting that JAK2V617F might be sufficient for the development of PV, increasing evidence shows that PV is not solely initiated by JAK2V617F. The fact that JAK2V617F has been identified in patients with three phenotypically related but clinically distinct MPN suggests that additional genetic or epigenetic events likely contribute to the phenotypic divergence of these disorders. These differing disease phenotypes have been hypothesized to be caused by striking differences in the degree to which the mutation activates the JAK–STAT pathway. Mutant JAK2 activates multiple cytokine receptor associated pathways, including STAT1 and STAT5, which can have competing consequences. STAT1 appears to be activated in association with JAK2V617F ET but not PV. Inhibition of STAT1 in ET progenitor cells enhances erythropoiesis, indicating that in ET, the phospo-STAT1 response to JAK2V617F constrains erythropoiesis and promotes megakaryocytic differentiation, but in PV, the reduced pSTAT1 response removes the break on erythropoiesis, allowing enhanced erythropoiesis to occur. The means by which JAK2V617F could lead to MPNs was further explored by examining SNPs for the glucocorticoid receptor (GR). The GR is encoded by a polymorphic gene on human chromosome 5q31-32. This polymorphism produces up to 256 combinations of alternative GR homodimers and heterodimers, which are variably expressed in the human population. Differences in ligand or DNA-binding affinities among isoforms are emerging as the leading cause of heterogeneity in body mass and in the response to GR ligands during stress. One of these polymorphisms is represented by the A3669G single-nucleotide polymorphism (SNP) in exon 9 of GR, which stabilizes the mRNA and increases the expression of GRβ (half-lives of A3669G+ and A3669G− GRβ mRNA are >6 and <6 hours, respectively). On ligand activation, GRα migrates to the nucleus both as homodimers and as heterodimeric tetrameric protein complexes with several signaling molecules, including the phosphorylated form of STAT-5. In the nucleus, GRα binds not only glucocorticoid-responsive elements but also elements that are responsive to each type of glucocorticoid complex. GRβ by contrast binds poorly to glucocorticoids because its unique structure impairs the ligand-binding domain and induces nuclear retention. Therefore, it does not form complexes with other signaling partners, including the phosphorylated form of STAT-5, and by forming heterodimers with GRα, it impairs ligand binding of this isoform and acts as a dominant negative regulator of GR function within the cells. The A3669G polymorphism, which stabilizes GRβ mRNA, had greater frequency in PV and MF patients than in normal control participants or patients with essential thrombocythemia. It has been suggested that JAK2V617F may be responsible for activation of alternative GR splicing in MPN EBs. After the alternative splicing is activated, the presence of the A3669G polymorphism, by stabilizing GRβ mRNA, may favor its translation, generating amounts of protein adequate for GRα neutralization, resulting in expansion of the erythroid precursor pool and delaying terminal differentiation, thereby contributing to the development of erythrocytosis in PV.

The role of JAK2V617F in the underlying pathogenesis of PV has been extensively explored using either restricted fragment length polymorphism analysis or the presence of marker cytogenetic abnormalities in patients with MPNs. It was demonstrated that the percentage of granulocytes and platelets that are JAK2V617F positive is often lower than the percentage of granulocytes belonging to the malignant clone. In addition, these marker cytogenetic abnormalities may occur before or after the acquisition of JAK2V617F. Furthermore JAK2V617F-negative erythroid colonies have been cloned in vitro in the absence of the addition of EPO, a hallmark of PV, indicating the presence of an undefined molecular lesion that precedes the JAK2V617 mutation.[15] These findings suggest that the acquisition of JAK2V617F is a relatively late event that is preceded by another genetic event that leads to clonal hematopoiesis. The acquisition of the JAK2V617F apparently occurs in this background of clonal hematopoiesis. Additional information that indicates that JAK2V617f is a relatively late event in the multistep pathogenesis of PV is the observation that the blasts cells from patients with JAK2V617F AML are negative for this mutation in 50% of instances, suggesting that the leukemia originates in residual normal stem cells or in the preJAK2 V617F clone. This observation is discussed in greater detail in Chapter 69.

Several investigators have reported families in which multiple members have an MPN and have analyzed the JAK2V617F status of family members. The members of 72 families with multiple members with MPN were analyzed for *JAK2V617F* mutational status. Somatic *JAK2V617F* mutations were identified in some, but not all, family members with MPNs. Interestingly, in some families, both *JAK2V617F*-positive and -negative members with MPN were observed. A small number of relatives who were JAJ2V617F negative and did not have a diagnosis of PV, ET, or PMF had hematopoietic cells that formed endogenous erythroid colonies in vitro. Disease evolution can be highly variable within families presenting with the same type of MPN. These results suggest that an as yet unidentified genetic event, either germline or somatic, might contribute to the pathogenesis of PV, ET, and PMF, regardless of *JAK2* mutational status, and that there may be "initiating events" that precede the acquisition of *JAK2V617F* in these disorders. Acquired mutations of the ten–eleven translocation 2 gene *(TET2)* that are discussed in greater detail in Chapter 69 were studied in these families to determine if it was a gene that played a role in PV before acquisition of JAK2V617F. These acquired *TET2* mutations occur in approximately 12% of patients with sporadic MPNs. The frequency and types of *TET2* mutations in patients with familial MPNs were similar to that observed in sporadic MPNs. As a whole, 20% of the family members with JAK2V617F MPN have *TET2* mutations, and 17% of JAK2V617F-negative members had a MPN with a *TET2* mutation. In addition, the *TET2* mutation may occur either before or after the acquisition of JAK2V617F. When JAK2V617F coexisted with *TET2,* the *TET2* allele burden varied from 20% to 60%. Different *TET2* mutations were observed in affected members of the same family and were shown to be acquired, indicating that *TET2* mutations are not a major predisposing factor to either sporadic or familial MPNS. Familial clustering of MPNs supports the evidence that the pathological phenotype is driven by yet to be defined susceptibility genes. Germline mutations in PHD2, which were discussed earlier, have been documented in occasional families with multiple family members affected by JAK2V617F MPNs. Mutated PDH2 has been proposed to be capable of acting as a tumor suppressor gene, but whether it plays any role in predisposing to familial MPNs will require further study. The germline constitutive JAK2 haplotype, called GGCC or 46/1, has been shown to be a susceptibility factor for the development of JAK2V617F-positive PV and PV characterized by exon 12 mutations.[16] How this JAK2 SNP promotes the development of typical MPNs remains the subject of great

speculation, but two hypotheses have been proposed: (1) hypermutability of the chromosome region facilitates the acquisition of somatic mutation, or (2) the JAK2 SNP confers a selective proliferative advantage, the so-called fertile ground hypothesis.

The JAK2V617F Mutation Is Present in Hematopoietic Stem Cells in Polycythemia Vera

Previous studies had demonstrated that the majority of patients with PV had clonal involvement of multiple lineages, including myeloid, erythroid, and lymphoid cells. These results suggested that PV originates in hematopoietic progenitors with the ability to differentiate into multiple lineages. In addition, LOH at 9p24, now known to correspond to homozygous JAK2V617F mutations, can be identified in both myeloid and lymphoid cells in some patients with PV, further suggesting that the underlying mutations occur in progenitor cells with the ability to differentiate into multiple hematopoietic lineages.

The JAK2V617F mutation has been detected in hematopoietic colony-forming cells and more mature progeny, such as neutrophils and platelets. Populations of cells enriched for HSCs, common myeloid progenitors (CMPs), granulocyte–macrophage progenitors (GMPs), and megakaryocytic–erythroid progenitors (MEPs) from patients with PV have been analyzed for the presence of the *JAK2V617F* mutation. *JAK2V617F* was detected in HSCs, CMPs, GMPs, and MEPs from patients with PV, supporting that PV is a disorder that arises in HSCs and involves the myeloid, erythroid, and megakaryocytic lineages. These data indicate that the *JAK2V617F* mutation in PV originates in lymphomyeloid progenitor cells.[17] The functional effects of the *JAK2V617F* mutation on HSC or precursor cells has been the subject of conflicting data originating from several laboratories with some investigators indicating that JAK2V617F is associated with an expansion of the HSC with skewing of the differentiation program toward the erythroid and megakaryocytic differentiation program and others indicating that JAK2V617F leads to expansion of more differentiated erythroid and megakaryocytic precursor cells but not stem cells. The expansion of JAK2V617F-positive cells has been attributed to responses to tumor necrosis factor-α (TNF-α). MPNs are characterized by increased levels of TNF-α, and JAk2V617F-positive HPCs compared with HPCs with wild-type JAK2, have been shown to be resistant to the inhibitory effects of this cytokine, thereby selecting for the malignant clone and facilitating its expansion.

Structural and Functional Aspects of JAK2V617F-Mediated Transformation

The *JAK2V617F* mutation occurs within the JH2 domain of JAK2, which has significant homology to the kinase domain of JAK2 (JH1) but lacks catalytic activity (see Fig. 67-4). The JH2 domain exerts an inhibitory effect on JAK2 kinase activity, and the V617F mutation is predicted to disrupt this inhibition. In vitro kinase assays with JAK2V617F and wild-type JAK2 have revealed that JAK2V617F has greatly increased kinase activity, as assessed by autophosphorylation and by substrate phosphorylation. Ectopic expression of JAK2V617F in either epithelial or hemopoietic cell lines results in autophosphorylation of mutant JAK2, but not the wild-type (WT) JAK2, and activation of downstream signaling events. BAF3 or FDCP cell lines expressing the EPOR and engineered to stably express JAK2V617F are largely independent of the addition of exogenous growth factors and are hypersensitive to EPO. Coexpression of JAK2 V617F and a homodimeric type 1 cytokine receptor (EPOR, TPOR, or G-CSFR) facilitates the transformation of cells to growth factor independence, suggesting that the mutant JAK2 requires a receptor scaffold to be active. This contrasts with the effects of the *TEL–JAK2* fusion gene, which can readily transform cells on its own, presumably because of the strong homodimerization effects of the TEL moiety. Ectopic expression of JAK2V617F can also sensitize cells to the effects of IGF1, a characteristic feature of PV progenitors.

Expression of JAK2V617F in hematopoietic cells activates intracellular signaling pathways downstream of the EPOR, including STAT5, STAT3, the MAP kinase pathway, and the phosphatidylinositol 3-kinase (PI3K)–Akt pathway.[18] STAT5 is normally phosphorylated by the cytokine receptor–JAK2 complex, and phosphorylated STAT5 then translocates to the nucleus and activates the transcription of target genes. The target genes of STAT5 include Bcl-X_L, an important antiapoptotic protein known to be expressed in increased levels in PV proerythroblasts. The possibility that STAT5-mediated activation of Bcl-X_L is important in the pathogenesis of PV was suggested by observations that expression of either constitutively active STAT-5 or Bcl-X_L resulted in spontaneous erythroid colony formation. In normal cells, DNA damage increases the activity of an amiloride-sensitive sodium hydrogen exchange isoform 1, which raises the intracellular pH, which in turn causes nonenzymatic deamidation of Bcl-xL. The deamidation pathway has been shown to be inhibited in a variety of MPNs, including PV, leading to less apoptosis. Interestingly, this defect in deamidation was reversed by treatment with a JAK2 inhibitor, suggesting that this defect might be a consequence of mutated JAK2. Furthermore, the degree of apoptosis can also be altered by p53 levels. JAk2V617F appears to functionally inactivate p53 by upregulating MDM2, an E3 ubiquitin ligase, thereby decreasing the degree of apoptosis. In addition, cells expressing JAK2V617F display constitutive activation of the MAP kinase pathway (as assessed by phosphorylation of ERK), and of the PI3K pathway (as assessed by phosphorylation of AKT). Furthermore, JAK2 has been shown to play a role in cellular myeloproliferative leukemia virus oncogene (MPL) trafficking. JAK2V617F might also lead to the decreased expression of mpl by platelets observed in PV patients. Furthermore, JAK2V617F and activated STAT5 have been shown to increase the expression of 6 phosphofructokinase/fructose-2,6 bisphosphatase 3 (PFKFB3), which controls glycolytic flux through 6-6-phosphofructo-1-kinase. PFKB3 is required for JAK2V617F-dependent lactate production, oxidative metabolic activity, and glucose activity, thereby promoting cell proliferation. It is important to note that many other oncogenic tyrosine kinases activate the same signal transduction pathways, and the role and requirement for each of these signaling pathways in the transformation of hematopoietic cells by JAK2V617F remain unknown. Although once thought to reside strictly in the cytoplasm of cells, a growing body of evidence indicates that both JAK1 and JAK2 are present in the nucleus of certain cells under conditions associated with high rates of cell proliferation. Nuclear JAKs have been reported to affect gene expression by activating other transcription factors besides STATs and influencing epigenetic events by phosphorylating H3 and activating global gene expression. JAK2V617F may alter chromatin structure by selectively phosphorylating the arginine methyltransferase PRMT5, impairing PRMT5 methyltransferase activity by negatively affecting its association with methylsome protein 50. Reduced PRMT5 activity increases HPC proliferation and promotes erythroid differentiation.

Many PV patients have a low burden of *JAK2V617F* as assessed by DNA sequencing, suggesting that there is either a subpopulation of cells that are homozygous for *JAK2V617F* mixed with wild-type cells or a clonal population of cells with one wild-type copy of *JAK2* and one mutant copy of *JAK2*. In PV, data from clonality or quantitative *JAK2V617F* assessment and from colony assays suggest that most PV patients have a subpopulation of cells homozygous for *JAK2V617F*, but in ET, clonal progenitor cells are heterozygous for *JAK2V617F*. It is therefore important to determine whether the wild-type allele can interfere with the ability of JAK2V617F to constitutively signal in the heterozygous state and whether there is an effect of gene dosage on the activation of signal transduction pathways. Transient coexpression of wild-type JAK2 does not interfere with the ability of JAK2V617F to autophosphorylate even when wild-type JAK2 is expressed at higher levels than the mutant kinase. This suggests that JAK2V617F kinase activity is unaffected by coexpression of wild-type JAK2. In contrast, when JAK2V617F and wild-type JAK2 were coexpressed in Ba/F3 cells, cytokine-independent growth was attenuated, suggesting in this cellular context that wild-type JAK2 is able to

interfere with JAK2V617F-mediated transformation. SOCS proteins bind to the JH1 catalytic loop and target JAK2 for degradation.[19] SOCS1 and SOCS3 bind to the catalytic groove belonging to JAK2 and inhibit its catalytic activity. SOCS3 binds to the EPOR and JAK2 to inhibit EPOR signaling. SOCS proteins inhibit JAK2 by functioning as E3 ubiquitin ligases. Although SOCS1, SOCS2, and SOCS3 inhibit phosphorylation of wild-type JAK2, they are incapable of blocking phosphorylation of JAK2V617F. On the basis of their findings, SOCS3 appears to be unable to inactivate JAK2V617, and SOCS3 itself is not degraded but accumulates and actually promotes the further phosphorylation of JAK2V617F. Such dysregulation likely enhances JAK2V617F-induced cell proliferation and prolongs signaling. These data have been suggested as an explanation for why JAK2V617F hematopoiesis predominates in PV heterozygotes. Low levels of JAK2V617F signaling in JAK2V617F heterozygotes likely induce SOCS3, which would downregulate JAK2 wild-type signaling and enhance signaling by JAK2V617F, permitting the malignant clone to predominate.

Additional Mutations Associated With Polycythemia Vera

After the application of whole-genome assays (comparative genomic hybridization and SNPs) as well as whole-genome sequencing, an increasing number of mutations have been observed in the patients with Philadelphia chromosome–negative MPNs. These mutations are not unique to any of the MPNs and are associated with AML and MDS.[18] Four of these genes—*EZH2, ASXL, DNMT3a,* and *TET2*—participate in the epigenetic control of transcription and are discussed in greater detail in Chapter 69. *EZH2* mutations occur in 3% of PV patients, 7% to 16% of PV patients have *TET2* mutations, and 5% to 7% have mutations of *DNMT3a; ASXL* mutations are rare in PV (<7%). Each of these mutations may precede JAK2V617F, but the converse may also occur. Each of these mutations are far less frequent in PV and ET than PMF, supporting that these events may combine to generate a more accelerated phase of the classic MPN that phenotypically presents as MF. In addition, several other mutations, including IDH1/2, IKZF deletions, NRAS/KRAS, p53 mutations, and RUNX1 mutations, rarely occur in PV but are all associated with transformation of an underlying MPN such as PV to acute leukemia.

The Hypercoagulable State That Characterizes Polycythemia Vera

Thrombosis is a major cause of morbidity and mortality in PV patients. These thrombotic events are most frequently microcirculatory and arterial, but venous thromboses are also of important clinical significance. The increased risk for thrombosis can be attributed to abnormalities in the vessel wall, blood cell components, and the dynamics of blood flow.

In the European Collaboration on Low-Dose Aspirin in Polycythemia Vera (ECLAP) study, the incidence of cardiovascular complications was higher in patients older than 65 years (5.0% of patients per year; hazard ratio [HR], 2.0; confidence interval [CI], 1.22-3.29; $P < .006$) or with a history of thrombosis (4.93% of patients per year; HR, 1.96; 95% CI, 1.29-2.97; $P = .0017$). Patients both with a history of thrombosis and older than 65 years had the highest risk of developing additional cardiovascular events (10.9% of patients per year; HR, 4.35; 95% CI, 2.95-6.41; $P < .0001$).[20] These data confirm previous findings that increasing age and history of thrombosis are the two most important prognostic factors for the development of vascular complications.

This information does not negate the increased incidence of thrombotic incidents also observed in younger patients with this disorder. In a series of 58 PV patients younger than 40 years of age, a disturbingly high incidence of life-threatening thrombotic events was observed. In fact, seven of the 10 patients in this series who died during the period of observation died from thrombotic events—four from Budd-Chiari syndrome, one from a pulmonary embolism, and two from cerebral thrombosis. Therefore, although a significant factor, preexisting atherosclerotic disease is not the sole etiologic factor in the genesis of thrombosis in PV. Some have suggested an important role for smoking as a secondary factor leading to the increased incidence of thrombotic events in this patient population.

The principal hemorrheologic abnormality in PV is an elevated whole blood viscosity. The blood viscosity in PV is higher than that of normal control participants at all shear rates. In a retrospective analysis of PV patients with histories of vascular thrombosis, a strong correlation in univariate analysis between hematocrit level and the development of thrombotic episodes, including many cerebrovascular occlusions, was demonstrated. Cerebral blood flow is reduced in patients with PV in whom the hematocrit level is 53% to 62%. These abnormalities were observed even in patients with hematocrits at the lower levels of normal, that is, 46% to 52%. Reductions in cerebral blood flow are correctable with phlebotomy. Reduction of the hematocrit by relatively small amounts frequently led to substantial improvements in whole blood viscosity and cerebral blood flow. Some PV patients apparently still maintain a higher than normal whole blood viscosity despite the normalization of the hematocrit, suggesting that an increase in hematocrit may not be the only factor responsible for increased blood viscosity. There appear to be important gender differences as related to the location of thromboses in PV patients. Women appear to have a higher incidence of thromboses within the abdominal cavity involving the portal, mesenteric, or hepatic vessels but a comparable rate of other vascular complications. Several groups have reported that patients with splanchnic vein thromboses frequently have endothelial cells that are affected by JAK2V617F, suggesting that in such individuals, their MPN might originate not at the level of the HSC but rather at the level of a hemangioblast, from which myeloid and endothelial cells originate. Such JAK2V61F-positive endothelial cells have been shown to exhibit a high efficiency of adhering to normal mononuclear cells, thereby likely leading to an increased risk of thrombosis.

A number of possible explanations have been suggested for the observed relationship between hematocrit level and the development of thrombotic events in PV patients. Platelet adhesion and thrombus formation on the vascular subendothelium are determined in part by the rate at which platelets are transported to the vascular surface. In a polycythemic condition in which increased numbers of RBCs are present, a greater number of intercellular collisions between RBCs and platelets occurs. These collisions could lead to increased platelet movement in a direction perpendicular to blood flow. This facilitation of platelet transport to the vessel wall may be an important factor in the development of thrombosis. An alternative explanation for the association between hematocrit level and the risk of thrombosis is based on the knowledge that blood viscosity is particularly sensitive to hematocrit levels. Increased hematocrits lead to increased blood viscosity, in turn leading to increased peripheral vascular resistance and an actual reduction in blood flow to a variety of organs, predisposing them to the development of thrombosis. The issue of hematocrits and thrombosis in PV has been prospectively investigated in a recent analysis of 1638 patients enrolled in the ECLAP study. In this prospective study, despite recommendations of maintaining hematocrit levels fewer than 45%, only 50% of patients achieved this target during the follow-up, and 10% had hematocrit levels above 50%. These different hematocrit values were not associated with different thrombotic outcomes as assessed using univariate and multivariable analysis. The clinical significance of this finding appears to be relevant for the construction of future therapeutic guidelines and is being validated in prospective randomized clinical trials. Additional factors have been implicated in the development of thrombosis in PV patients. Almost all patients with PV are iron deficient. Decreased RBC deformability has been said to accompany iron deficiency, leading to increased blood viscosity and a decreased ability of RBCs to pass through small-bore polycarbonate filters. This increased membrane stiffness, however, might be counterbalanced by the effect of a reduced RBC size on the adherence of blood platelets to arteriolar

subendothelium. RBC size is a major determinant of platelet adherence, with larger RBCs leading to increased platelet adherence and smaller RBCs to decreased platelet adherence. Whether the increased membrane stiffness associated with iron deficiency is counterbalanced by the decreased platelet adherence associated with smaller RBCs is yet to be determined.

Thrombocytosis and qualitative platelet abnormalities occur frequently and are likely to be important contributory factors to the development of thrombosis.[21] Some investigators have implicated uncontrolled thrombocytosis as a cause of thrombosis in these patients, but this relationship has not been confirmed by others. Increased plasma and urinary thromboxane production has been linked to increased platelet activation in these patients. A low-dose aspirin regimen selective for inhibition of platelet cyclooxygenase has been found to suppress increased thromboxane production in vivo and to clinically benefit patients with PV. Furthermore, elevated levels of serum VEGF and plasma TPO have been observed in patients with PV. These growth factors have been shown to lead to platelet activation.

Despite conflicting data, no clear clinical relationship between platelet number or function and the incidence of hemorrhage or thrombosis in PV patients has been delineated. An argument in favor of a role of elevated platelet numbers in the genesis of thrombosis in PV and ET is the observation in patients with ET that a reduction of excessive platelet numbers with the use of hydroxyurea is associated with a reduction in the risk of developing thrombotic events. However, this should not be taken as evidence that the reduction in developing additional vascular events was caused by platelet count normalization alone; very likely, it may be related to the suppression by hydroxyurea of each of three myeloid lineages. In line with this interpretation are the results of a randomized study performed by the Medical Research Council in the United Kingdom (PT-01) in which patients with ET were randomized to receive either hydroxyurea or anagrelide therapy. This study showed that hydroxyurea therapy rather than anagrelide, a selective platelet number–reducing drug, was associated with a reduction in the number of arterial thrombotic events, especially in JAK2V617F patients. In a recently reported analysis of the ECLAP study, the rate of thrombosis in PV patients during follow-up did not vary according to different platelet numbers. Select patients with PV have, however, been afforded prompt resolution of vascular complications such as erythromelalgia or TIAs after institution of platelet antiaggregating agents or cytoreduction. It is important to emphasize that erythromelalgia does not resolve in PV patients with phlebotomy alone or with anticoagulation but requires the use of platelet antiaggregating agents or reduction of platelet numbers. What distinguishes the clinical courses of these patients from those of others is unknown. These reports coupled with the knowledge of abnormal thromboxane metabolism of platelets in PV provide substance to the belief that platelets contribute to the generation of the thrombotic and hemorrhagic tendencies observed in PV. Although a number of clinical assessments of platelet function have been used to identify patients who are potentially at a high risk of developing a life-threatening hemorrhagic or thrombotic event, the results of these studies to date have been very disappointing. It appears that the etiology of thrombosis and hemorrhage in PV is multifactorial and that the available tools are inadequate to identify patients at highest risk.

An elevation of WBC number occurs in 50% to 60% of PV patients, which may also have a detrimental effect on the rheology of the microcirculation in PV. An analysis of the ECLAP database showed that a baseline WBC count above $15{,}000 \times 10^6\ L^{-1}$ was associated with the development of major arterial events, mainly myocardial infarction. Similar results were shown in two additional studies in patients with ET. Activated leukocytes may release proteases and oxygen radicals that alter endothelial cells and platelets so as to favor the development of a prothrombotic state. A series of markers of leukocyte activation, including expression of membrane CD11b and leukocyte alkaline phosphatase antigen, cellular elastase content, plasma elastase levels, and myeloperoxidase levels, are elevated in patients with PV. Limited and conflicting data are available as to whether or not there is a correlation between the presence of platelet–leukocyte interactions and thrombotic events. Moreover, the association between these functional abnormalities and the presence of JAK2V617F is unclear. Increased expression of leukocyte adhesion molecules increases the adhesion of leukocytes to platelets and the endothelium. These cell to cell interactions stimulate the activation of endothelial cells and platelets and induce the release from activated leukocytes reactive oxygen species as well as proteases that are capable of impairing a number of hemostatic processes. Platelet–leukocyte aggregates are increased in number in PV and are associated with an increased propensity to thrombose. In addition, the prothrombotic state in PV has been attributed to an acquired resistance to the naturally occurring anticoagulant, protein C, which is associated with reduced levels of protein S. The loss of protein S in PV patients is especially profound in those with a high JAK2V617F allele burden, but its cause remains unknown, although some have speculated that it is the consequence of the degradation of protein S by the increased levels of neutrophil elastase. PV patients with a high allele burden may represent a subpopulation with a particular high risk of developing a thromboembolic event.

Polycythemia Vera and the Risk of Hemorrhage

Patients with PV are also at an increased risk of developing life-threatening hemorrhagic complications. Abnormalities in platelet function and number have been implicated as the cause of this hemorrhagic tendency. Qualitative platelet abnormalities frequently found in these patients include platelet hypofunction as demonstrated by defective in vitro platelet aggregation, acquired storage pool disease, platelet membrane defects, increased platelet reactivity as demonstrated by enhanced platelet aggregation, increased plasma β-thromboglobulin levels, and shortened platelet survival. With platelet counts greater than $1000 \times 10^9\ L^{-1}$, the development of acquired von Willebrand syndrome has been reported and is associated with life-threatening hemorrhagic episodes.

Post–Polycythemia Vera Myelofibrosis and Acute Myeloid Leukemia

A major cause of morbidity and mortality in PV results from the transition from the polycythemic phase of the disease to post-PV MF and to acute leukemia. Post-PV MF is characterized by cytopenias, MF, and extramedullary hematopoiesis. In a variety of MPNs, the fibroblastic component of the BM has been shown not to be directly involved in the malignant process but to be a reactive event to the neoplastic clone. Several investigators have suggested that the release of growth factors, particularly platelet-derived growth factor (PDGF), fibroblast growth factor, and transforming growth factor-β from megakaryocytes or platelets, which are present in abundance in patients with MPNs, might be responsible for this fibroblastic proliferation. Whether the use of any particular therapeutic agents for treatment of PV accelerates the development of PV related MF remains hotly debated, although it is well established that the use of alkylating agents such as piprobroman or chlorambucil increases the risk of developing acute leukemia. It remains a source of debate if treatment with hydroxyurea increases the risk of developing MF or AML. The bulk of evidence does not support a clear leukemogenic role for this drug that is the standard of care for high-risk PV patients. Nevertheless, as a cautionary principle, it is wise to consider carefully the use of this agent in very young subjects and in those carrying cytogenetic abnormalities and to avoid it in pregnant women and in patients previously exposed to alkylating agents. In a recent report in which patients were treated exclusively with hydroxyurea with an average follow-up of 16.3 years, the cumulative incidence of AML/MDS in the patients treated with hydroxyurea alone was 7.3%, 10.7%, and 16.6% at 10, 15, and 20 years, respectively, and was significantly lower than in patients treated with the alkylating agent piprobroman.[22] However, patients treated with hydroxyurea had a

greater chance of developing MF (at 20 years, 31.6% vs. 21.3%). Whether hydroxyurea really is leukemogenic is difficult to say from this study because such long-term follow-up of patients not receiving any chemotherapeutic agents is not available; the possibility therefore exists that these rates of evolution merely reflect the natural history of the disease. In 50% of cases of JAK2V617F MPNs, the blast cells that represent the progeny of the leukemia-initiating clone are JAK2V617F negative, suggesting that the leukemia originates from a clone distinct from the JAK2V617F-positive clone. This coexistent JAK2V617F-negative clone appears to have a higher propensity to undergo leukemic transformation. JAK2V617F therefore does not appear to be a prerequisite for leukemic transformation of MPNs, suggesting that additional genetic events are required for full transformation to occur. SNP–array analysis has shown that genomic alterations occur at an increased frequency during the period of blastic transformation and that no single gene or molecular pathway is sufficient to cause transformation. A surprising correlation has been observed between the phenotype of the preceding MPN and the JAK2 mutational status of the leukemic blasts after transformation. In contrast to JAK2 wild-type AML in this setting, evolution to JAK2V617F-positive leukemias is invariably preceded by a myelofibrotic transformation of ET/PV or JAK2V617F-positive PMF. Because of these observations, myelofibrotic transformation of ET or PV is thought by many to represent an accelerated phase of the initial MPN preceded by genetic changes that result in evolution to MF and eventually leukemia. JAK2 wild-type leukemia, by contrast, usually arises in patients with chronic phase PV or ET that do not undergo evolution to MF. Some have suggested that these leukemias are therapy related. The reversion from JAK2V617F to wild-type JAK2 in these leukemias has been shown not to be caused by homologous recombination. Two models have been proposed to account for the clonal relationship between JAK2 wild-type AML and its preceding MPN: (1) both the chronic MPN and the AML arise from a shared pre-JAK2V617F founder clone and (2) the chronic MPN and the AML arise from two independent stem cells (Fig. 67-6).It remains possible that each model is viable and operates in different individual patients.

CLINICAL MANIFESTATIONS

The principal clinical manifestations of PV can largely be attributed to the excessive production of cells belonging to each of the myeloid lineages affected by the malignant process, including RBCs, platelets, and WBCs. With the implementation of laboratory tests during annual physical examinations, increasing numbers of people are being diagnosed with PV before the symptoms related to this neoplastic process become apparent. Symptomatic patients with PV may present to a physician with a myriad of nonspecific complaints, including headaches, weakness, pruritus, dizziness, excessive sweating, visual disturbances, paresthesias, joint symptoms, abdominal distress, a thrombotic or hemorrhagic episode, and weight loss. Thrombosis is a frequent presenting event. Two-thirds of such thrombotic events occur either at presentation or before diagnosis and the remainder most often during the first 10 years of follow-up. At diagnosis, one-third of patients have already lost 10% of their body weight, presumably secondary to the hypermetabolism associated with this disorder, and complaints of fatigue are common. Arthropathies are frequently observed and are largely caused by the clinical manifestations of gout. The hyperproliferative BM state characteristic of PV and the increased nucleoprotein degradation are contributory factors in the development of hyperuricemia.

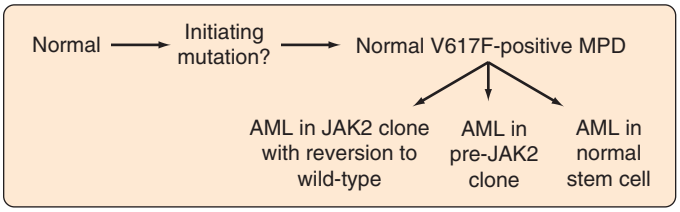

Figure 67-6 MODELS FOR THE DEVELOPMENT OF JAK2V617F-NEGATIVE ACUTE MYELOID LEUKEMIA (AML) FROM JAK2V617F-POSITIVE MYELOPROLIFERATIVE DISORDER (MPD). Three possible models are shown, in which $V617F^-$ AML could develop from (1) a $V617F^+$ cell that subsequently reverts to $V617F^-$, (2) a cell that had some other initiating mutation before *JAK2,* or (3) a normal stem cell. *JAK,* Janus kinase. *(From Campbell PJ, Baxter EJ, Beer PA, et al: Mutation of JAK2 in the myeloproliferative disorders: Timing, clonality studies, cytogenetic associations, and role in leukemic transformation.* Blood *108:3548, 2006.)*

The principal findings on physical examination of a patient with PV include ruddy cyanosis, conjunctival plethora, hepatomegaly, splenomegaly, and hypertension.

Untreated patients are at particularly high risk for thrombotic and hemorrhagic events. In several large series of patients with PV, thrombosis was the cause of death in 30% to 40% of patients. Arterial thrombotic events account for two-thirds of such events, with venous thrombotic events representing the remainder. Ischemic stroke, myocardial infarction, and TIAs are the most common arterial thrombotic events. Patients may also present with deep venous thrombosis in the lower extremities, pulmonary embolism, or peripheral vascular occlusions. The cumulative rate of thrombosis ranges from 2.5% to 5% per patient per year. The prevalence of thrombosis at diagnosis ranges from 34% to 39%. It is not unusual for patients with PV to develop thromboses at unusual anatomic sites; in particular, thromboses are relatively frequent in the splanchnic veins, including the splenic, hepatic, portal, and mesenteric vessels or cerebral sinus veins, thrombosis of the vena cava, and intraventricular thrombosis. A particularly serious thrombotic event associated with PV is Budd-Chiari syndrome, which results from hepatic venous or inferior vena caval thrombosis and obstruction. These events lead to hepatic venous outflow obstruction, increased hepatic sinusoidal pressure, and portal hypertension. Portal venous perfusion of the liver is frequently reduced, leading to portal venous thrombosis and hypoxic damage of liver parenchymal cells. This cascade of events results in centrilobular hepatic necrosis, centrilobular fibrosis, and nodular regenerative fibrosis, which culminates in the development of cirrhosis of the liver. The cause of Budd-Chiari syndrome can be identified in 75% of cases, including hereditary and acquired prothrombotic disorders, trauma, and infection. PV account for 10% to 40% of all cases of Budd-Chiari syndrome. Paroxysmal nocturnal hemoglobinuria is also a frequent cause of Budd-Chiari syndrome. Because BM cells from 87% of patients with idiopathic Budd-Chiari syndrome form erythroid colonies in the absence of EPO, such patients were in the past believed to have a forme fruste of an MPN. The identification of these latent MPNs, without elevated blood counts, has been facilitated by screening for JAK2V617F. These patients tend to be younger and female and to have normal blood counts caused by hemodilution and hypersplenism, which mask an elevated RBC mass.[23] Many of these patients (37%) also have another predisposing factor for thrombosis such as exposure to oral contraceptives, antiphospholipid antibodies, factor V Leiden, or protein C deficiency. The JAK2V617F mutation has been reported in 32.7% patients of 831 patients with an idiopathic splanchnic vein thrombosis. The mutation was present in 49% of patients at diagnosis of the idiopathic form of splanchnic vein thrombosis of which 60% were diagnosed as having a coexisting MPN; more than 52% of the remaining patients went on to develop an MPN after a median of 49 months. JAK2V617F was detected in 45% of patients with Budd-Chiari syndrome, and at least in one series, neither exon 12 JAK2 mutations nor MPL mutations were observed. Furthermore, additional patients (6.9%) have idiopathic splanchnic vein thrombosis who have a BM histopathologic picture diagnostic of an MPN but are JAK2V617F negative. The diagnostic value of low serum EPO level in Budd-Chiari syndrome has been questioned because elevated levels have been attributed in JAK2V617F-positive patients to necrotic liver tissue.

There are fulminant, acute, subacute, and chronic forms of Budd-Chiari syndrome. These clinical manifestations depend on the extent and rapidity of hepatic vein occlusion and the development of venous

collaterals to decompress the venous sinusoids. One should always consider a diagnosis of Budd-Chiari syndrome in any patient with an MPN with ascites, upper abdominal pain, and liver function abnormalities. This syndrome is characterized by hepatosplenomegaly, ascites, edema of the peripheral extremities, and distention of superficial abdominal veins caused by resultant portal hypertension. Routine biochemical determinations of hepatocellular function and injury are frequently of little diagnostic value in patients with suspected Budd-Chiari syndrome. Doppler ultrasonography is the best tool for screening patients for Budd-Chiari syndrome. This test has a sensitivity and specificity of 85%. Characteristic findings include an absence of flow in the hepatic veins or nonvisualization of the hepatic vein. Contrast-enhanced computed tomography (CT) scanning and magnetic resonance imaging (MRI) are useful in better defining the hepatic venous anatomy. Hepatic venous and inferior vena caval catheterization is a key diagnostic procedure indicating the sites of venous obstruction. The diagnosis can be definitively made by a spider web pattern on hepatic venography. Transjugular liver biopsy specimens usually reveal intense congestion and cellular atrophy.

It has been emphasized that patients with PV can present with portal or hepatic vein thrombosis with normal hemoglobin or hematocrit values. Such patients have leukocytosis, thrombocytosis, or splenomegaly. Screening for the JAK2 mutation should be systematically carried out in such situations and may substitute for BM examinations in individuals who are JAK2V617F positive. In patients with an idiopathic form of splanchnic vein thrombosis but who are JAK2V617F negative, a BM aspirate and biopsy are recommended to exclude the possibility of a JAK2V617F-negative MPN. Gastrointestinal bleeding or an increase in plasma volume that is a consequence of splenomegaly often accounts for the normal blood counts in such patients with Budd-Chiari syndrome. The factors operational in the PV patient that lead to the development of hepatic vein thrombosis are believed to be multiple. Whereas splenomegaly causes increased portal blood flow, extramedullary hematopoiesis within the hepatic sinusoids frequently obstructs hepatic blood flow, and JAK2V617F-positive endothelial cells might affect adhesion to monocytes, leading to aggregation of blood elements. These processes are surely important contributory factors in addition to the other previously discussed risk factors that lead to the development of thrombosis in this patient population.

Neurologic abnormalities occur in almost 60% to 80% of untreated or poorly controlled PV patients and include TIAs, cerebral infarction, cerebral hemorrhage, fluctuating dementia, confusional states, and choreic syndromes. In addition, complaints of dizziness, paresthesias, visual disturbances, tinnitus, and headaches have been attributed to the increased blood viscosity and reduced cerebral blood flow caused by erythrocytosis. The transient neurologic symptoms can also be the consequence of small infarcts in the region of the basal ganglia, which can be detected by CT. These small infarcts are known as lacunae and result from the occlusion of small penetrating arteries, which are particularly susceptible to thrombosis. Cerebrovascular thrombosis occurs more often in PV patients than in the general population. Symptoms caused by intermittent carotid or vertebral basilar artery insufficiency (or both) occur so frequently in PV that it is suggested that every patient with focal cerebrovascular insufficiency should at least have a complete blood count test to exclude the diagnosis of an underlying MPN.

Thrombosis of the dural sinus or cerebral veins (CVT) is an uncommon form of stroke, usually affecting young individuals. CVT represents about 0.5% to 1% of all strokes. Headache, generally indicative of an increase in intracranial pressure, is the most common symptom in CVT. Clinical manifestations of CVT may also depend on the location of the thrombosis. The superior sagittal sinus is most commonly involved, which may lead to headache, increased intracranial pressure, and papilledema. A motor deficit, sometimes with seizures, can also occur. Scalp edema and dilated scalp veins may be seen on examination. For lateral sinus thromboses, symptoms related to an underlying condition (middle ear infection) may be noted, including constitutional symptoms, fever, and ear discharge. Pain in the ear or mastoid region and headache are typical. Hemianopia, contralateral weakness, and aphasia may sometimes be seen owing to cortical involvement. Approximately 16% of patients with CVT have thrombosis of the deep cerebral venous system (internal cerebral vein, vein of Galen, and straight sinus), which can lead to thalamic or basal ganglial infarction. Cavernous sinus thrombosis is usually associated with a primary infectious etiology involving a focus in the face, throat, mouth, ear, or sinuses. Aseptic cavernous sinus thrombosis is an extremely rare phenomenon that has been reported in patients with PV. These patients present with monocular blindness and the characteristic features of ipsilateral cavernous sinus thrombosis, and only retrospectively is the diagnosis of PV made. Therefore, patients found to have this symptom complex who have no known infectious predisposing causes should be carefully evaluated to rule out this diagnosis. The most sensitive diagnostic technique is MRI in combination with magnetic resonance venography.

Thrombosis of large-caliber arteries is a relatively rare event in PV patients, but there have been case reports of thromboses within the chambers of the heart, leading to refractory congestive heart failure and acute aortic occlusion. Such catastrophic thrombotic events in the heart or large vessels would suggest that cardiac catheterization be performed with some caution.

Polycythemia vera frequently manifests with symptoms caused by peripheral vascular disease. In these cases, patients may first be seen by surgeons or dermatologists. Intense redness or cyanosis of the digits with or without burning, classic erythromelalgia, digital ischemia with palpable pulses, or thrombophlebitis without another known cause may be the presenting symptoms.

Erythromelalgia is characterized by burning pain in the digits, an objective sensation of increased temperature, and relief by cooling. PV is the most common cause of erythromelalgia and is one of the few disorders in which digital ischemia with or without ulceration may exist in the presence of palpable pulses. Other disorders that can lead to this abnormality include embolism, trauma, cutaneous infarction, neuritis, infection, and various types of arteritis. Painful and ulcerating toes and fingers have frequently been observed to be presenting symptoms in patients with PV. The likelihood that arterial insufficiency is the cause of such ulceration is quite small in patients who have a palpable dorsalis pedis and posterior tibialis pulses; in this situation, the possibility of an underlying hematologic disorder such as PV should be entertained. Foot pain at rest is a distressing but not widely recognized symptom of PV. In patients with this complaint, peripheral pulses are of normal character, and cutaneous circulation appears to be adequate. The pain is most severe at night, is dull in nature, and occurs primarily in the feet or legs. These symptoms have been shown to be the results of platelet activation and aggregation in vivo, which preferentially occur in arterioles. If untreated, erythromelalgia can progress to ischemic acrocyanosis or gangrene. Phlebotomy alone in PV does not improve erythromelalgia. These symptoms can be abolished by reducing the platelet counts to normal levels and can be rapidly reversed after the institution of antiplatelet aggregation therapy. Therefore, the cause of erythromelalgia appears to be closely linked to abnormal arachidonic acid metabolism that occurs within platelets in this disorder.

Retrospective reviews have revealed a higher than expected number of patients with PV and pulmonary hypertension. Proposed etiologies include direct obstruction of pulmonary arteries by circulating megakaryocytes, extramedullary hematopoiesis in the pulmonary parenchyma, smooth muscle hyperplasia induced by release of PDGF from activated platelets, chronic disseminated intravascular coagulation, and unrecognized recurrent thrombotic events. ET-1 has been associated with development of hypoxia-related pulmonary hypertension and VEGF with protection from this complication. The diagnosis of pulmonary hypertension is made, on average, 9.5 years after the diagnosis of the underlying MPN and is associated with a poor prognosis, with death usually occurring as a result of congestive heart failure or pneumonia. Although anecdotal reports have claimed improvements in patients' pulmonary artery pressure with control of the underlying disease, others have not found any change in serial measurements of 11 patients' pulmonary arterial pressures despite good disease control.

As many as 30% to 40% of patients with PV experience some sort of hemorrhagic event, which can be relatively trivial, such as epistaxis or gingival hemorrhage, or can be life-threatening, such as gastrointestinal hemorrhage or hematomas involving vital organs. The gastrointestinal tract is a frequent site of hemorrhagic complications because patients with PV are predisposed to portal vein thrombosis and resultant variceal bleeding and peptic ulcer disease. Gastroduodenal erosions and ulcers and *Helicobacter pylori* infection are all significantly more common in PV patients than in control patients with dyspepsia. This may be partly attributable to altered mucosal blood flow as a result of increased plasma viscosity or increased histamine release caused by peripheral blood basophilia. Cerebral hemorrhage is a common cause of morbidity and mortality. Bleeding events frequently occur with the use of aspirin or other drugs that impair platelet function; an association between the hemorrhage and the use of high doses of these platelet-paralyzing drugs has been made in almost one-third of such instances. Low-dose aspirin therapy has, however, been reported not to lead to an increased incidence of life-threatening hemorrhagic events. Spontaneous bleeding in patients with PV is relatively rare, although spontaneous retropharyngeal hematomas leading to acute upper airway obstruction or hematomas in the groin have been reported.

Patients with PV who undergo surgical procedures are at a very high risk of developing postoperative complications. In one series of 62 major operations on 54 patients with PV, postoperative complications occurred in 49% of patients; 52% of complications were from hemorrhage, 18% from thrombosis, and 14% from hemorrhage and thrombosis. The postoperative mortality rate in this patient population was 18%. In another series of 15 patients five had serious complications secondary to thrombosis and hemorrhage. A study by an Italian group evaluated retrospectively 311 surgical interventions in 105 patients with PV and 150 with ET: 24 arterial or venous thrombosis (7.7%), 23 major hemorrhages (7.3%), and five surgery-related deaths (1.6%) were observed within 3 months of the procedure. PV patients with uncontrolled erythrocytosis before surgery have been shown to have the highest complication rate. Patients with inadequately controlled disease had a 79% incidence of complications, but in those with adequate hematologic control before surgery, the rate of perioperative and postoperative complications was reduced to 28%. In addition, the duration of disease control was an important factor in decreasing surgical risk; a prolonged period of effective disease control before surgery reduced the complication rate to 5%. Complication rates after surgery can therefore be dramatically reduced by appropriate therapeutic interventions with normalization of blood counts. The chief deterrent to such an approach has been the failure by physicians to recognize the risk associated with PV in the surgical setting.

Generalized pruritus occurs in approximately 40% of cases of PV. Water contact, such as during showers or bathing, induces attacks of intolerable pruritus. There appears to be no clear relationship between the degree of the pruritus and severity of the disease, and 20% of patients continue to experience itching despite reduction of their hematocrits to normal levels. Aquagenic pruritus is significantly more common among JAK2V617F homozygous patients than heterozygotes. The degree of pruritus is so severe in some patients that they are unable to tolerate bathing at all and find it necessary to substitute gentle skin swabbing or to simply not bathe. The etiology of the pruritus in PV remains uncertain. Several groups have attempted to implicate elevated blood and urine histamine levels in its pathobiology. A strong correlation between skin mast cell numbers and the severity of itching has been demonstrated, and mast cells in PV have been shown to be JAK2V617F positive. However, the failure of the pruritus to respond to antihistamine therapy in many patients suggests that abnormally high histamine levels probably do not constitute the sole factor in its development.

Iron deficiency has also been implicated as a factor contributing to pruritus in PV patients who are almost invariably iron deficient. Iron substitution therapy has resulted in symptomatic improvement, but this approach is less than optimal because it frequently results in uncontrollable erythrocytosis.

The development of post-PV MF was increased with prolonged duration of disease and is directly related to the duration of long-term follow-up, but the influence of the modality used to treat the initial PV phase of the disease on the rate of transformation to this more accelerated form of the disease remains uncertain. Post-PV MF should be considered the natural evolution of PV. Criteria for the diagnosis of post-PV MF have recently been proposed (Table 67-3) and can be used as a guide for documenting this transition in disease phenotype, which in reality represents a point in the continuum of PV. For patients with disease duration greater than 10 years, the hazard ratio was 15.24 (95% CI, 4.22-55.06; $P < .0001$). The median interval between the diagnosis of PV and the development of post-PV MF is 13 years. Post-PV MF is characterized by (1) increasing splenomegaly, (2) teardrop RBC morphology, (3) extensive BM fibrosis, (4) a leukoerythroblastic blood picture, and (5) a normal or decreasing RBC mass. The patients may be entirely asymptomatic but often complain of fatigue, dizziness, weight loss, and anorexia. Splenomegaly can lead to abdominal pain caused by repeated splenic infarcts and to early satiety caused by mechanical obstruction of the upper gastrointestinal tract. Patients with post-PV MF are virtually all JAK2V617F positive and characteristically have high JAK2V617F allele burdens (see Chapter 69).

The anemia that characterizes post-PV MF is primarily a result of splenic pooling, ineffective erythropoiesis, and extramedullary production of RBCs with a shortened RBC survival. Patients positive for JAK2V617F are less likely to require blood transfusions but have a poorer survival. Occasionally, the anemia is exacerbated by folate or iron deficiency. Before assuming that a patient has entered post-PV MF, it is prudent to assess BM iron stores. Replacement therapy with iron may lead to the resurgence of erythropoiesis and prevent the faulty categorization of disease progression.

Bleeding abnormalities caused by thrombocytopenia or qualitative platelet abnormalities are especially common during this phase of the disease. Frequent instances of epistaxis or ecchymoses occur, and gastrointestinal hemorrhage caused by esophageal varices arising from portal hypertension is a recurrent problem. The majority of hemorrhagic events are minor in nature. Frequently, patients have generalized wasting characterized by progressive asthenia and weight loss. Severe hyperuricemia, leading to secondary gout or uric acid nephropathy, may also complicate the clinical course.

The median survival for patients with post-PV MF is 5.7 years. Patients with post-PV MF are at a high risk for the development of

Table 67-3 International Working Group for Myelofibrosis Research and Recommended Treatment Criteria for Post-PV MF

Required Criteria:
1. Documentation of a previous diagnosis of polycythemia vera as defined by the WHO criteria
2. Bone marrow fibrosis grade 2–3 (on 0–3 scale) or grade 3–4 (on 0–4 scale)
Additional Criteria (Two Are Required):
1. Anemia or sustained loss of requirement of either phlebotomy (in the absence of cytoreductive therapy) or cytoreductive treatment for erythrocytosis
2. A leukoerythroblastic peripheral blood picture
3. Increasing splenomegaly defined as either an increase in palpable splenomegaly of ≥5cm (distance of the tip of the spleen from the left costal margin) or the appearance of a newly palpable splenomegaly
4. Development of ≥1 of three constitutional symptoms: >10% weight loss in 6 months, night sweats, unexplained fever (>37.5°C)

Adapted from Proposed criteria for the diagnosis of post-polycythemia vera and post-essential thrombocythemia myelofibrosis: A consensus statement from the international working group for myelofibrosis research and treatment. *Leukemia* 22:437, 2008.
WHO, World Health Organization.

acute leukemia. Of patients who develop post-PV MF, approximately 18% will undergo leukemic transformation after 3 years and likely a greater number with longer follow-up. Patients with post-PV MF with a hemoglobin less than 10 g/dL, platelet count less than 100×10^9 and WBC counts that exceed 30×10^9/L have a poorer prognosis than individuals with fewer of these prognostic variables.

The leukemic transformation of PV has been extensively described. The possibility that a relationship exists between the therapeutic modality used during the erythrocytotic phase and the frequency of development of acute leukemia has been a point of heated discussion. Some of the controversy surrounding this question was formerly caused by a lack of understanding of the basic origins of PV. Clinical hematologists in the 1950s and 1960s frequently thought of PV as a benign hematologic abnormality and believed that therapeutic interventions either with alkylating agents or radiotherapy were solely responsible for the development of acute leukemia. That concept has proved erroneous, and PV, similar to the other MPNs, has been shown to be a clonal malignant hematologic disorder. The evolution to acute leukemia can therefore be thought of as a natural consequence of this malignant disorder, which can be accentuated by the therapeutic interventions already discussed. In fact, 25% of patients who develop MPNs have never been exposed to any form of cytotoxic therapy.

Further insight into the relationship between acute leukemia and PV has been best provided by the results of the PV Study Group (PVSG), which described a randomized trial comparing the use of phlebotomy, chlorambucil, and ^{32}P for the treatment of this disorder. The incidence of acute leukemia was approximately 1.5% in patients treated with phlebotomy alone, 17.5% in patients treated with chlorambucil, and 10.9% in patients treated with ^{32}P after over 15 years of follow-up. The incidence of acute leukemia in the patients treated with phlebotomy alone is therefore much higher than that expected in a normal age-matched control group, again indicating that leukemia is a natural evolutionary event in the clinical course of an individual with PV. The incidence of acute leukemia can be increased, however, by the institution of therapy with either alkylating agents or ^{32}P. The time course for the development of acute leukemia appears to be dependent on the treatment used to control the polycythemia. The development of acute leukemia in patients treated with phlebotomy in the PVSG trial was limited to the first 5 years of treatment, suggesting that the development of acute leukemia is not solely attributable to the prolongation of survival. In contrast, analysis of the hazard function was virtually flat for patients treated with chlorambucil from years 2 to 7 after randomization; however, the risk for acute leukemia became alarmingly high after 10 years of study, suggesting that the risk of acute leukemia increases with time even after the drug has been stopped. One half of the cases of acute leukemia in the chlorambucil arm occurred in the first 5 years, with the remainder equally split between the second and third 5-year periods. In contrast, 60% of the cases of acute leukemia in the group treated with radioactive phosphorus occurred 6 to 10 years after randomization. Of particular concern is the high incidence of leukemia recently reported in patients who were initially treated with radioactive phosphorous or busulphan and then switched to maintenance therapy with hydroxyurea, previously believed to be a nonleukemogenic agent. These findings suggest that a combination of radiotherapy (^{32}P) or an alkylating agent, busulphan, and another chemotherapeutic agent (hydroxyurea) may particularly increase the risk of leukemia. Approximately 30% to 50% of patients with PV who develop acute leukemia have previously entered the post-PV MF phase. In contrast, approximately 50% of patients progress directly from the erythrocytotic phase to acute leukemia. The phenotype of the leukemia cells that characterize the leukemic phase is overwhelmingly myeloid, although rare cases of lymphoblastic and biphenotypic leukemias have been reported. Patients with JAK2V617F-positive MPN are also at a higher risk of developing both additional hematologic malignancies and solid tumors. In addition, low-grade lymphoproliferative disorders such as chronic lymphocytic leukemia have been shown to coexist in patients with a variety of MPNs, including PV, and not to have an adverse effect on prognosis.

The development of leukemia sometimes can be abrupt, however. In some instances, a preleukemic phase characterized by refractory anemia with excess blasts has been described. In fact, half of such cases of acute leukemia in one series were preceded by a myelodysplastic disorder.

A surprising finding that provides some insight into the origins of acute leukemia occurring in PV patients has been provided from studies of the JAK2V617F status of the leukemia blast cells of such patients. Surprisingly, in about 50% of these patients, the leukemic cells were JAK2V617F negative even though in excess of 90% of the PV patients are JAK2V617F positive. Patients with JAK2V617F-positive MPN who developed JAK2V617F-negative leukemias had a shorter time between the diagnosis of the original MPN and the leukemic transformation (3 + 2 vs. 10 + 7 years, respectively) than patients with JAK2V617F-positive leukemias. The possible origins of JAK2V617F-negative leukemias from JAK2V617F-positive MPNs are diagrammatically presented in Fig. 67-6. The AML could potentially originate in the normal stem cell pool that persists in MPD patients, or it could originate in a malignant clone that has not acquired the JAK2V617F mutation. The other possibility remains that the chronic MPN and the AML represent two subclones originating from a common ancestor and that the leukemic transformation results in loss of JAK2V617F.

LABORATORY MANIFESTATIONS

Laboratory evaluation of patients with erythrocytosis involves the careful use of a broad range of diagnostic studies. These studies must be used in a rational manner or the evaluation can become extremely costly. Because PV is a panmyelosis, the overwhelming number of patients has elevated hematocrits, WBC counts, and platelet counts. The diagnosis of PV has been greatly simplified by the discovery of the JAK2V617F mutation, which is present in more than 90% of PV patients. Hematocrit values greater than 52% in males and greater than 48% in females are abnormal and require further evaluation. Documentation of the absolute increase in RBC mass is rarely required and is a test that is available at smaller and smaller numbers of institutions. A hematocrit value greater than 60% in men or greater than 55% in women is almost always associated with an absolute erythrocytosis. In men suspected of polycythemia with a hematocrit level below 60% and women with a hematocrit level below 55%, blood volume measurement is suggested, if available, for determining whether the elevated hematocrit level is actually attributable to an expanded RBC mass. Occasionally, an elevated RBC mass can actually be present in the face of a normal hematocrit value. In cases of splenomegaly caused by portal hypertension, an expanded plasma volume may mask an elevated RBC mass. In addition, iron deficiency can also lead to a normalization of the hematocrit in PV, making the diagnosis difficult. PV is associated with a 20% to 30% frequency of peptic ulcers and gastritis, which can be associated with blood loss. In this situation, thrombocytosis may be exacerbated as a consequence of the iron deficiency. Iron supplementation is not necessary to make a diagnosis of an MPN because of the availability of molecular diagnostic studies. Administration of iron to such patients must be performed carefully to avoid a rapid increase in RBC mass, which can be associated with a high risk of thrombosis. If the patient is JAK2V617F positive and has microcytosis and iron studies indicative of iron deficiency, one can be certain that the patient has an MPN, which is likely PV. The true type of MPN will become apparent with continued follow-up.

The criteria for establishing an RBC mass has previously been based on values expressed as milliliters per kilogram of total body weight. Because adipose tissue is considerably less vascular than lean tissue, it may not contribute equally to the RBC mass. Therefore, RBC mass measurements based solely on body weight can be misleading. RBC mass measurements more closely correlate with lean body mass than total body weight. Measured RBC mass values in obese subjects are regularly lower when expressed as milliliters per kilogram of total body weight than those observed in lean individuals. To

overcome this difficulty, the International Council for Standardization in Haematology has presented formulas to calculate normal RBC mass values based on lean body mass, surface area, height, and weight. An elevated RBC mass is now defined as being 25% greater than the mean predicted value of an RBC mass for that individual rather than basing evaluations on the volume per kilogram of total body weight.

Leukocytosis is present in approximately two-thirds of cases and seems to be proportional to the burden of JAK2V617F. Thrombocytosis is observed in 50% of cases. Abnormalities of RBC, WBC, and platelet morphology are frequently observed. The morphologic RBC changes observed during the erythrocytotic phases are characteristic of iron deficiency and include microcytosis, hypochromia, and frequently polychromatophilia. Some anisocytosis and poikilocytosis can be seen as well. Fetal hemoglobin levels and the number of RBCs containing fetal hemoglobin, known as F cells, may be increased. The WBCs are characterized by normal morphology, although the numbers of basophils, eosinophils, and immature myeloid forms can be increased. Platelet morphology is also quite striking in PV. Frequently, megathrombocytes (platelets the sizes of RBCs) are seen on the peripheral blood smear. Patients frequently have platelet counts of less than 1×10^6 mm^{-3}, but it is not unusual to observe a patient with a platelet count higher than this value. PV-related MF is characterized by a leukoerythroblastic blood picture, with the appearance in the peripheral blood of dacryocytes or teardrop RBCs, myelocytes, metamyelocytes, and (rarely) blasts and promyelocytes in addition to nucleated RBCs in the peripheral blood.

Platelet aggregation studies do not correlate frequently with the risk of bleeding episodes. The most common abnormalities are decreased primary and secondary aggregation to either or both epinephrine and adenosine diphosphate and decreased response to collagen with generally a normal response to arachidonic acid. An abnormal platelet storage pool disease is a characteristic feature and is caused by abnormal platelet activation. Prothrombin times (PT) and partial thromboplastin times (aPTT), as well as fibrinogen levels, are usually normal. Profound abnormalities of the PT and aPTT, however, are frequently reported. This is largely a laboratory artifact caused by the extreme erythrocytosis, which results in a relatively smaller volume of plasma being present in the whole blood sample. Coagulation assays are performed on blood anticoagulated with sodium citrate, and the citrate concentration in the anticoagulant is calibrated to chelate the plasma calcium and inhibit coagulation reactions. All coagulation assays include the addition of calcium chloride to neutralize the excess citrate and provide free calcium to mediate coagulation reactions. In patients with extreme erythrocytosis, the ratio of citrate in the collection tube to the volume of plasma is too high; therefore, excess citrate is present, and the standard amount of calcium chloride added during the performance of the PT and aPTT is insufficient to neutralize the excessive citrate, and the coagulation assays are frequently and factually prolonged. To avoid this problem, the clinician should calculate the relative amount of plasma compared with the normal amount and remove the corresponding volume of sodium citrate from the blood collection tube. Normal values can then be confidently anticipated in patients with erythrocytosis. A shortened fibrinogen half-life has been detected in some patients with PV and a significantly increased fractional catabolic rate of the plasma fibrinogen pool per day. In addition, elevated platelet β-thromboglobulin and plasma β-thromboglobulin levels are observed. The constellation of findings is indicative of increased platelet turnover. Prothrombin fragments F1 and 2, thrombin–antithrombin complex, and D-dimer levels are frequently elevated in PV patients. These are enzyme–inhibitor complexes or byproducts of active thrombosis that serve as a biochemical signature of the hypercoagulable state that characterizes PV.

An acquired von Willebrand syndrome occurs frequently in patients with PV and ET who have extreme elevations of platelet numbers. This syndrome is characterized by a normal or prolonged bleeding time, normal factor VIII level, and normal von Willebrand factor (vWF) antigen level, but abnormal vWF ristocetin cofactor actively associated with a decrease or absence of large vWF multimers. This acquired defect resembles type II vWF disease. Because the molecular size of vWF is a major determinant of its adhesive function and the larger multimers are most active in achieving hemostasis, the deficiency of large vWF multimers is associated with a bleeding tendency. The decrease in the frequency of large vWF multimers occurs in patients with platelet counts over 1000×10^9 L^{-1}. This abnormality has been reported not only with patients with severe thrombocytosis caused by MPN but also in patients with reactive thrombocytosis. An inverse correlation between the proportion of large vWF multimers and platelet numbers has been observed. In addition, normalization of the platelet count is accompanied by restoration of a normal vWF multimer pattern. These findings suggest that thrombocytosis of any etiology may favor the adsorption of larger forms of vWF multimers onto platelet membranes, resulting in their removal from the circulation and subsequent degradation by platelet-associated proteases. Although patients with MPN frequently have bleeding tendencies, this is not the case in secondary thrombocytosis, possibly because of the limited periods of extreme thrombocytosis observed in such patients. Patients with PV with clinical courses punctuated by hemorrhagic events, extreme thrombocytosis, and acquired von Willebrand syndrome should not receive aspirin therapy if they are having a thrombotic episode but should be phlebotomized, and platelet reduction therapy should be initiated. Patients with PV and acquired von Willebrand syndrome have recurrent bleeding from mucous membranes and the digestive tract and easy bruisability. These symptoms frequently resolve with normalization of the platelet count.

Deficiencies of one or more natural anticoagulants as well as antiphospholipid antibody syndrome have been observed in patients with PV and thrombosis. These studies indicate that either familial or acquired antithrombin III deficiency, protein C or S deficiency, factor V Leiden mutation, or the prothrombin G gene mutation may contribute to the hypercoagulable state observed in PV. Of note, although hyperhomocysteinemia caused by deficiency of cobalamin or folate can be found in 32% to 56% of PV patients, there is no agreement as to its role in the genesis of thrombotic episodes. Such inherited disorders associated with the erythrocytosis of PV provide a scenario that frequently favors thrombosis in affected individuals. In attempting to determine if a patient with PV and an active thrombosis has such an inherited predisposition, it is important to be aware that proteins C and S as well as antithrombin III levels can be low in patients with an ongoing acute thrombosis or liver cirrhosis. Normal prothrombin and factor VII levels in such patients eliminate liver cirrhosis as a cause of the reduction of these circulating anticoagulants. Individuals with inherited prethrombotic conditions frequently have levels of specific proteins below 10% to 20% of normal during periods of active thrombosis.

The leukocyte alkaline phosphatase activity level is elevated in 70% of patients. Moreover, recent data indicate an increase of neutrophil elastase levels in granulocytes and in plasma that correlates with JAK2 mutational status. Whereas serum vitamin B_{12} concentrations have been found to be elevated in 40% of patients, serum vitamin B_{12}–binding proteins are elevated in 70% of patients. Hyperuricemia occurs in an overwhelming number of patients, and elevated histamine levels are also frequently observed. BM aspirates and biopsies obtained at the time of diagnosis of patients with PV are hypercellular and display characteristic erythroid, granulocytic, and megakaryocytic hyperplasia. The cellular elements (Fig. 67-7) are frequently morphologically normal. Iron stores are almost uniformly absent in pretreatment biopsy specimens. Significant increases in BM reticulin may be present in biopsies obtained early in the course but also may develop during the erythrocytotic phase and may be present for long periods before the onset of the post-PV MF. It is important to emphasize that individuals may have considerable BM fibrosis, which occurs as a consequence of the underlying MPN. The presence of minimal BM fibrosis should not be considered a harbinger of the development of post-PV MF. In patients with post-PV MF, a moderate to marked increase in reticulin fiber is observed, either simultaneously with or within 1 year of this clinical transformation.

Several investigators have attempted to use BM biopsy morphology as a differential diagnostic tool to differentiate between PV and

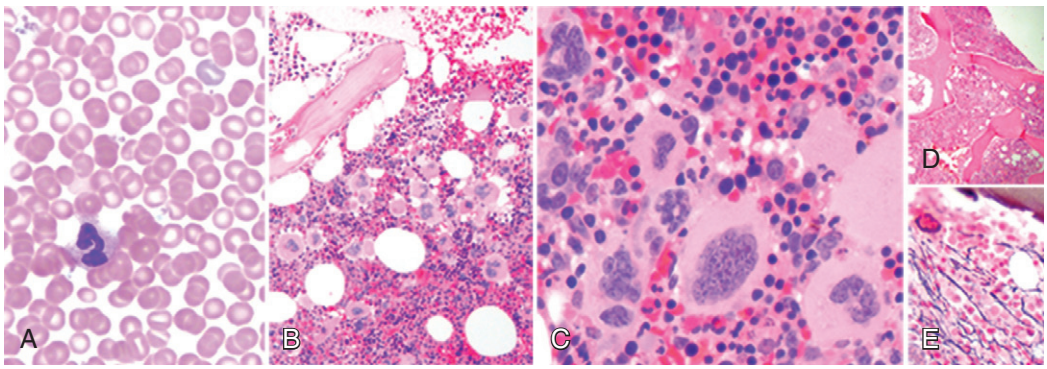

Figure 67-7 PHOTOMICROGRAPH OF BONE MARROW BIOPSY OBTAINED FROM A PATIENT WITH POLYCYTHEMIA VERA IN MYELOFIBROTIC PHASE DEMONSTRATING HYPERCELLULARITY AND INCREASED NUMBER OF MEGAKARYOCYTES (×160).

secondary forms of erythrocytosis. The marked hypercellularity and megakaryocytic hyperplasia that are the hallmarks of MPNs are useful parameters for identifying such individuals (see Fig. 67-7). It is imperative to use the BM biopsy rather than the aspirate specimens for this purpose. It has been suggested that those PV patients with minor BM fibrosis are at an increased risk to develop a thrombotic episode or to evolve into post-PV MF but not acute leukemia during the course of their disease.

The pathologic appearance of the spleen in PV depends on the stage of the disease at which the organ is examined. Spleens from patients in the erythrocytotic phase of the disease are characterized by striking congestion with mature erythrocytes. Small numbers of hematopoietic precursor cells are frequently present. By contrast, spleens examined during the PV-related MF phase are characterized by prominent numbers of foci of extramedullary hematopoiesis, with representation of all BM precursor elements.

The proliferative capacity of PV HPCs has been shown to be a useful laboratory adjunctive study. PV HPC form endogenous erythroid colonies in vitro, which is a tool that can be used to study patients with features of PV who are JAK2V617F negative or who do not have an exon 12 mutation of JAK2. It is important to emphasize that although the presence of endogenous colonies in the blood is indicative of PV, the inability to detect these colonies does not entirely eliminate the diagnosis. Assays of BM cells are indicated when endogenous colonies are not detectable in the peripheral blood. Because of the lack of quality assurance in the performance of such clonal erythroid progenitor cell assays in some laboratories, some reservations concerning their widespread use as diagnostic tools have been expressed.

Allele-specific PCR methods can be used to detect the JAK2V617 or an JAK2 exon 12 mutation in approximately 95% of patients with PV. The very high frequency of JAK2V617F in PV has dramatically improved our ability to diagnose this disease. Patients with isolated erythrocytosis associated with normal neutrophil and platelet counts but low serum EPO levels and the formation of erythroid colonies by peripheral blood mononuclear cells in the absence of EPO in vitro are the characteristic phenotype of patients with the exon 12 mutation. BM biopsies from these patients were slightly hypercellular with isolated erythroid hyperplasia. Megakaryocytes were morphologically normal and not clustered. The exon 12 mutations were frequently present at low levels in granulocyte DNA but were readily identifiable in endogenous erythroid colonies generated in vitro. Because granulocyte involvement with JAK2 exon 12 mutations is low, it is important to sequence DNA from BM cells or from endogenous erythroid colonies generated in vitro to make this diagnosis. At diagnosis, serum EPO levels in PV are either reduced or at the lower limits of normal. Even after normalization of the hematocrit, the serum EPO level in PV remains low in two thirds of patients.

Arterial blood gas measurements are frequently performed to rule out hypoxia as a cause of erythrocytosis. In PV with extreme thrombocytosis, such routine measurements can prove to be misleading. Spurious hypoxemia can frequently be attributed to either significant leukocytosis or thrombocytosis caused by in vitro consumption of oxygen, the so-called platelet and leukocyte larceny. In this situation, pulse oximetry can be a useful tool for establishing the patient's true oxygenation status.

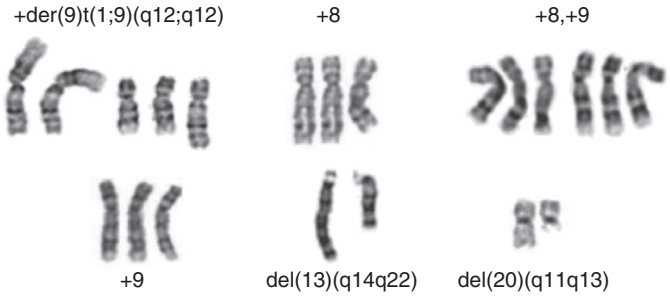

Figure 67-8 Most frequent chromosomal abnormalities associated with polycythemia vera at diagnosis include *(top row)* a gain of derivative(9)t(1;9), resulting in three copies of the long arms of chromosome 1 and three copies of the long arms of chromosome 9, including Janus kinase 2 (JAK2); gain of chromosome 8 and simultaneous gain of both chromosomes 8 and 9 *(bottom row);* gain of chromosome 9 alone; interstitial deletion of chromosome 13, c; and interstitial deletion of chromosome 20.

CYTOGENETIC ABNORMALITIES

The occurrence of nonrandom cytogenetic abnormalities in PV is anticipated because this is a feature of most hematologic malignancies. Such abnormalities have been observed without a single characteristic abnormality defined; the most frequent abnormalities are the gain of chromosome 9 as well as 9p, deletion of chromosome 20q, gain of the long arms of chromosome 1, trisomy 8, and deletion of chromosome 13 (Fig. 67-8). Balanced translocations are rarely observed in PV. At diagnosis, approximately 28% of patients have a recurrent clonal chromosome marker. Interphase fluorescence in situ hybridization (FISH) testing with eight probes for loci most frequently associated with PV and other Ph-negative MPNs occasionally identifies cryptic +9p, del(20q) or del(13q) abnormalities and thus may increase the frequency of detecting a chromosomal rearrangement at diagnosis to 29% to 30%.[24] However, interphase FISH (I-FISH) does not appear to significantly increase the detection rate in untreated patients. Among 387 patients with PV cytogenetically studied at the authors' institution between 1984 and April 2011, 28% had cytogenetic abnormalities at diagnosis. I-FISH studies alone (without cytogenetic examination) using an MPN panel of 12 probes revealed that 29% of patients had genomic changes (Fig. 67-9). The frequency of detection of cytogenetic abnormalities in PV increases over time, with 35% to 55% of patients having clonal cytogenetic abnormalities after extended follow-up and more than 80% of those patients in whom acute leukemia eventually develops. The detection

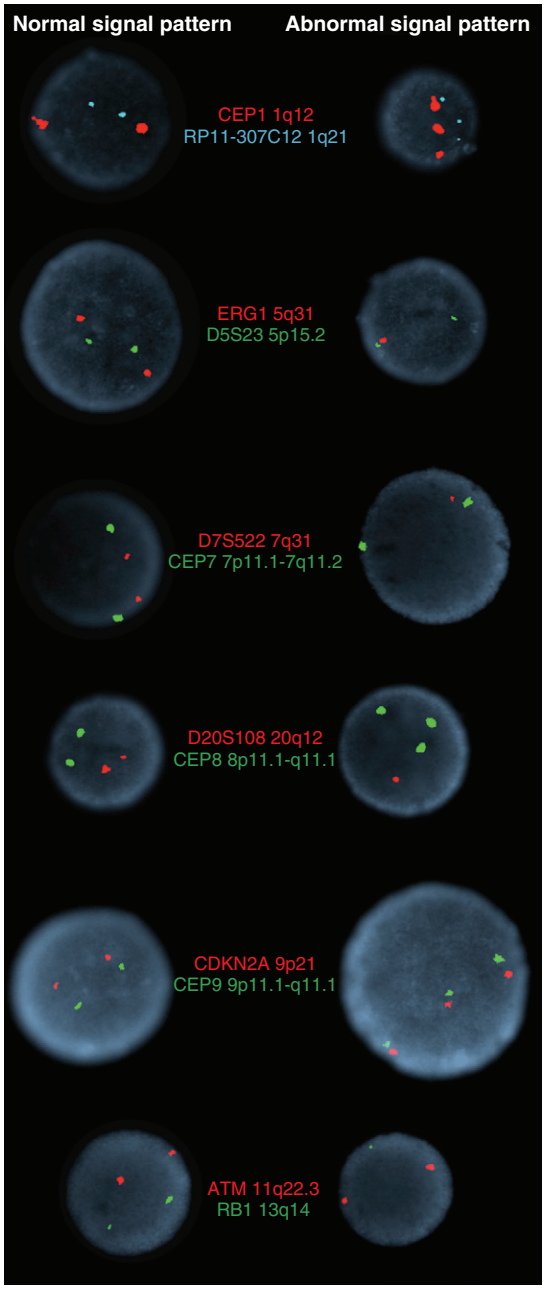

Figure 67-9 Myeloproliferative neoplasm fluorescence in situ hybridization (FISH) panel includes 12 loci on eight different chromosomes for detection of the most frequent chromosomal rearrangements when cytogenetics are either not available or in conjunction with conventional cytogenetics for detection of cryptic abnormalities. Discrepancy in frequency of abnormality detected by interphase FISH and conventional cytogenetics are present and often suggest a proliferative advantage of the abnormal clone.

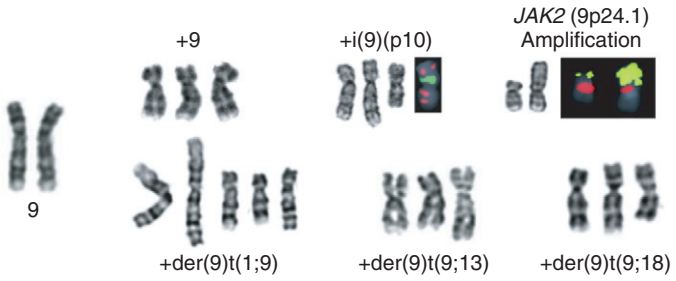

Figure 67-10 Numerous chromosomal abnormalities resulting in trisomy, tetrasomy, or amplification of the short arms of chromosome 9.

of these abnormalities during the disease progression is higher with I-FISH because del(20q) or +9p may be associated with a proliferative advantage. Therefore, progression from a normal to abnormal karyotype is an important adverse prognostic parameter.

Trisomy of the long arms of chromosome 1 is a recurrent abnormality present in about 4% to 6% of patients with PV and an abnormal karyotype. This abnormality has also been described in PMF and other myeloid malignancies. Specifically, 70% of patients with post-PV MF develop trisomy 1q as a result of unbalanced translocations. There are three types of chromosome 1q abnormalities identified in PV: (1) unbalanced translocations such as der(1)t(1q;other chromosome); (2) duplication of the long arms, most frequently q21, q31-32 chromosomal regions; and (3) jumping 1q translocations. Trisomy 1q rarely occurs alone and is most frequently found translocated to another chromosome creating a balanced +1q translocation. The recipient chromosome most frequently involved is chromosome 6 followed by chromosome 9. Jumping translocations are rare cytogenetic phenomenon whereby a part of one chromosome is translocated to several recipient chromosomes, creating multiple related clones within a single patient. Jumping 1q in MPN occurs in 4.2% of cytogenetically abnormal MPN; 86% of such patients progress to AML after an average of 8 months. After it is acquired, the prognosis tends to depend on a copy number of 1q, suggesting that 1q jumping translocations are associated with both disease progression and poor prognosis.

Gain of chromosome 8 is a recurrent abnormality not only in Ph-negative MPN, but it is also one of the three most frequent abnormalities in MDS and is present in 10% of patients with malignant hematopoietic disorders of both myeloid and lymphoid lineages. The prognostic significance in PV is unknown. Some patients with PV with trisomy 8 do not acquire other abnormalities after 20 years. The simultaneous presence of both +8 and +9 is PV specific and is observed in 3% to 4% of PV cases; it is rarely seen in other hematologic malignancies. In PV, trisomy 8 has been demonstrated in myeloid cells but not in lymphoid cells. The genetic consequences of trisomy 8 are unclear, although recent studies suggested a role for microRNAs that are localized on chromosome 8. MicroRNAs are small noncoding RNAs (≈19-25 nucleotides in length) that act as regulators of gene expression by inducing translational inhibition and cleavage of target mRNAs.

Trisomy 9 and gain of the short arms of chromosome 9 is most frequently and almost exclusively observed in PV. There are three types of 9p abnormalities in PV: (1) about 30% of patients have uniparental disomy of 9p region; (2) numerical gain, such as different chromosomal rearrangements that contribute to trisomy, tetrasomy, or amplification of 9p; and (3) unbalanced translocations, of which the most frequent, +der(9)t(1;9), results in a trisomy of both 9p and 1q and appears to be relatively specific abnormality in PV patients (Fig. 67-10). This rearrangement provides an extra copy of mutated *JAK2*. Another recurrent and rare chromosome abnormality resulting in trisomy 9p and three copies of mutated *JAK2* is der(18)t(9;18)(p13;p11)/der(9;18)(p10;q10). I-FISH has been used to detect cryptic chromosome 9 rearrangements. FISH uncovered chromosome 9 rearrangements in 53% of patients with abnormal FISH patterns, indicating that a gain of 9p is the most frequent genomic alteration in PV. The association between the trisomy of 9p and PV was one of the keys to the identification of the JAK2V617F mutation. Cytogenetic studies of 9p and LOH do not indicate any terminal losses or deletions along the entire short arm of chromosome 9, indicating that the LOH is attributable to mitotic recombination. The prognostic significance of +9/+9p is still unknown.

Interstitial deletions of the long arms of chromosome 13 are not specific for PV and are more frequently observed in PMF than in PV. About 1% to 13% of cytogenetically abnormal patients with PV have del(13q). Among patients with del(13q), about 91% have breakpoints in 13q12-14 to q21-22 regions. Fine FISH mapping has defined the commonly deleted region to 13q13.3-q14.3

encompassing Rb1 and two microsatellite loci, D13S319 and D13S25. Cryptic del(13q) occurs and is easily identified with the FISH method. Deletions are heterogenous and may involve one, two, or all three loci, including Rb1. However, structural rearrangements of Rb1 have not been reported in patients with PV. Balanced translocations of 13q14 have rarely been reported in PV, and several studies have shown that submicroscopic deletions involving the same commonly deleted region as defined by del(13q) are present in those apparently balanced translocations.

Del(20)(q11q13), an interstitial deletion of the long arm of chromosome 20, is the second most common cytogenetic abnormality in PV (Fig. 67-11). Del(20)(q11q13) is not diagnostic of PV because it also occurs in PMF and ET as well as in MDS and AML. Heterogeneity of the breakpoints is suggested by the observation that two minimally deleted regions (MDRs) characterize different disorders. A 2.7-Mb spanning D20S10-8 (proximal) and D20S481 (distal) is identified in Ph-negative MPN, and a 2.6-Mb region spanning R52161 (proximal) and Wi-12515 (distal) region is found in other malignancies. Two commonly deleted regions (CDR), CDR1 spanning 2.4 Mb between bands 20q11.23 and 20q12 and CDR2 encompassing 1.8 Mb within 20q13.12, have been identified. The commonly retained region 1(CRR1) spans 1.9 Mb within 20q11.21 and CRR2 encompasses 2.5 Mb within 20q13.33.[25] High-resolution genotyping did not reveal any somatic copy neutral LOH within these regions. Because deletion of chromosomal material may result in the loss of one or several tumor suppressor genes, investigations to date of candidate genes within the deleted segments have failed to identify any mutations within deleted segments. In contrast, haploinsufficiency of the *L3MBTL1* gene, the human homolog of the *Drosophila* L(3)MBT polycomb group tumor suppressor gene located on the 20q12 within a region commonly deleted in several myeloid malignancies, may play a role in erythropoiesis in PV. Downregulation of the L3MBTL1 expression in primary hematopoietic stem progenitor cells (HSPCs), causes an enhanced commitment to and acceleration of erythroid differentiation. Moreover, overexpression of L3MBTL1 in primary hematopoietic $CD34^+$ cells as well as in 20q-cell lines limits erythroid differentiation. Knock-out of L3MBTL1 enhances the sensitivity of HSPCs to EPO, with increased EPO-induced phosphorylation of STAT5, AKT, and mitogen-activated protein kinase (MAPK) as well as detectable phosphorylation in the absence of EPO. Therefore, haploinsufficiency of L3MBTL1 may contribute to erythroid differentiation in PV. It has also been demonstrated that L3MBTL1 is important for the normal progression of cells through mitosis because both overexpression and loss of activity can affect cell division. There is evidence that 20q deletions may impair the release of granulocytes into the peripheral blood. Some patients with PV and 20q deletion in BM cells have cytogenetically normal peripheral blood granulocytes, which has been attributed to del(20q) cells being preferentially retained or destroyed in the BM. I-FISH and SNP-A greatly enhance detection of del(20q) not identified with metaphase cytogenetics. The significance of this abnormality remains unknown because it may be dormant for many years before cells with del(20q) gain proliferative advantage. It is important to emphasize, however, that patients with del(20q) have been observed without further karyotypic instability for more than 10 years.

Other rare recurrent chromosomal abnormalities may occur at the onset of the disease or are associated with disease progression. Most notable are interstitial deletions of the long arms of chromosomes 5 and 7; both have been reported at diagnosis and are associated with disease progression. Loss of P53 as a result of del(17p) or other chromosomal rearrangements is a rare finding in PV and appears to be related to disease progression. Deletion (17p) is not PV specific because it is found in many other myeloid malignancies.

One can conclude that chromosome abnormalities such as +8, +9, and del(20)(q11q13) might be related to the biogenesis of the disease rather than occurring as a consequence of the chemotherapy used to treat the patients. However, it appears that in some patients, an abnormal clone (abnormalities of chromosome 5, 7, or 17) develops as a consequence of therapy with chemotherapeutic agents. Some investigators have suggested that patients with cytogenetic abnormalities at diagnosis have a statistically significant poorer survival rate than those in whom a normal karyotype is observed. This influence of cytogenetic abnormalities on prognosis has, however, not been verified.

Genomic aberrations detected by high-resolution SNP microarray demonstrated that indeed many patients are genetically normal at diagnosis except for, as already mentioned, uniparental 9p disomy, which is detected in about 30% of PV patients. However, disease progression is characterized by an increased number of genomic changes, some of which may not be cytogenetically detectable.

Figure 67-11 A karyotype from a dividing megakaryocyte showing (*arrows*) two copies of deleted 20q in a cell with 92 chromosomes.

Moreover, in a limited number of patients tested, abnormal methylation pattern does not seem to play a crucial role in the pathogenesis of JAK2V617F mutation–positive PV.

DIFFERENTIAL DIAGNOSIS

In most patients, establishing the cause leading to erythrocytosis is not difficult. Initially, it is critical to be certain that one is dealing with a patient with an absolute erythrocytosis. A hematocrit level greater than 60% on several occasions in men or greater than 55% in women, however, is associated with an elevated RBC mass in virtually every case. Testing for JAK2V617F and JAK2 exon 12 mutations can be extremely useful in diagnosing PV and is now common practice to make a diagnosis in any patient who is suspected of having PV. The presence of splenomegaly is an important finding on clinical examination, and adjunctive laboratory findings include normal arterial oxygen saturation, elevated leukocyte alkaline phosphatase activity, and JAK2V617F assays. Splenic sizing by ultrasonography can be useful in documenting splenic enlargement when the spleen is not palpable by physical examination.

It is initially important to differentiate PV from the large number of other causes of secondary erythrocytosis. Characteristically, the patient with PV will present with erythrocytosis, leukocytosis, thrombocytosis, and splenomegaly and is positive for JAK2V617F. The BM biopsy shows hypercellularity with trilineage hyperplasia. In individuals with less pronounced disease, it is important to determine the SaO_2 using an arterial blood gas, the carboxyhemoglobin level, and the $P_{50}O_2$ in patients with other family members with erythrocytosis to exclude obvious causes of secondary erythrocytosis. Because smokers' polycythemia is the most frequent cause of erythrocytosis, it is wise to measure carboxyhemoglobin levels early on in the investigation. In addition, a PaO_2 greater than 67 mm Hg or an O_2 saturation greater than 95% as quantitated on an arterial blood gas is helpful in ruling out hypoxic conditions that lead to erythrocytosis. In patients with intermittent hypoxia, such as sleep apnea syndrome or alveolar hypoventilation caused by obesity, such blood gas determinations can be normal. A low $P_{50}O_2$ is indicative of a hemoglobin mutant with high O_2 affinity, leading to tissue hypoxia and erythrocytosis. These patients often have multiple family members with erythrocytosis. Tests that can be especially useful for this purpose are the serum EPO level, the ability of BM cells to form erythroid colonies in the absence of exogenous EPO, and a JAK2V617F determination. Patients with PV most frequently exhibit serum EPO levels below the 95% confidence intervals for the range observed in normal control participants. It is not unusual to have a normal EPO level in some patients with hypoxic causes of secondary erythrocytosis unless the hypoxia exists over an extended period of time. A normal EPO level cannot be used to exclude a hypoxic cause of erythrocytosis. EPO measurements do, however, remain an important diagnostic tool. Elevation of EPO levels in the face of erythrocytosis is indicative of a hypoxic cause of secondary erythrocytosis, but extremely low levels of EPO (<4 mIU/mL) are virtually diagnostic of PV. It is the patient with erythrocytosis and a normal EPO level in whom additional adjunctive diagnostic tests are required to define the cause of erythrocytosis. The availability of genetic markers such as JAK2V617 or JAK2 exon 12 mutations clearly expedite the diagnosis.

Incorporating a mutational screen into the algorithm for investigating a case of suspected polycythemia will help to streamline the diagnosis of PV, although the presence of a JAK2 mutation alone does not distinguish PV from PMF or ET. Clinical criteria for the diagnosis of PV have been defined by the World Health Organization (WHO), which serves as a uniform platform with which to diagnose PV. It is important, however, for the clinician to realize that some patients undoubtedly have an MPN disorder resembling PV but do not fulfill all the diagnostic criteria of the PVSG or the WHO. The criteria for the diagnosis of PV including the use of the JAK2V617 assay and histopathologic parameters have recently been provided by the WHO (Table 67-4). These criteria are the consensus of many experts working in this field and represent an advance in this field. There will always be unusual cases with clinical characteristics that cannot be pigeonholed into a particular diagnostic category. If asymptomatic; these patients should be followed carefully until the disorder evolves into a more recognizable entity. This would appear prudent to avoid unnecessary therapeutic interventions. If these patients have serious symptoms, the individual physician must make treatment decisions on the basis of the risk-to-benefit ratio for that patient.

A particularly difficult dilemma occurs when evaluating patients with isolated pure erythrocytosis. These patients have elevated RBC masses, normal WBC counts, normal platelet counts, no evidence of splenomegaly, and no evidence of any recognizable cause of secondary erythrocytosis. Clearly, some of these patients have JAK2V617F-positive PV or mutations of exon 12 JAK2 leading to isolated erythrocytosis. The familial congenital form of polycythemia caused by truncation of the EPOR, characterized by increased sensitivity of erythroid progenitor cells to EPO, can be easily distinguished from PV. These patients frequently present in childhood, and this disorder is characterized by isolated erythrocytosis that is associated with an increased risk of thrombotic events. There is a strong family history of polycythemia. In contrast to PV, the BM progenitor cells are hypersensitive to EPO, yet no colonies form in the absence of EPO. The patient with profound erythrocytosis but who is negative for JAK2V617F as well as exon 12 JAK2 mutations and does not have erythrocytosis caused by smoking, cyanotic heart disease, an EPO-secreting tumor, residing at a high altitude, or sleep apnea remains a diagnostic dilemma. All patients should have a good family and drug history obtained, an arterial oxygen saturation study and a carboxyhemoglobin measurement, and measurement or calculation of a p50 and quantitation of a 2,3BPG level and a serum EPO level. If these studies are unrewarding, these patients should then be investigated for mutations in the hypoxia-responsive element of the human EPO gene,HIF-2α and HIF-1α, VHL, PHD1,2,3, STAT5, LNK, and TET2. Some of these tests can be performed by commercial labs, but often one will have to contact an academic reference lab to complete such an extensive investigative effort.

Polycythemia vera must also be differentiated from the other MPNs, such as CML, ET, and PMF. Such classification has major prognostic implications and influences important therapeutic decisions, including the use of tyrosine kinase inhibitors such as imatinib,

Table 67-4 Proposed Revised World Health Organization Criteria for Polycythemia Vera

Diagnosis
Requires the presence of both major criteria and one minor criterion *or* the presence of the first major criterion together with two minor criteria.
Major Criteria
1. Hemoglobin >18.5 g/dL in men and 16.5 g/dL in women *or* another evidence of increased RBC volume*
2. Presence of *JAK2*V617F or other functionally similar mutation such as *JAK2* exon 12 mutation
Minor Criteria
1. Bone marrow biopsy showing hypercellularity with trilineage hyperplasia (panmyelosis) with prominent erythroid, granulocytic, and megakaryocytic proliferation
2. Low serum erythropoietin level
3. Endogenous erythroid colony formation in vitro

Data from Tefferi, Thiele J, Orazi A, et al: Proposals for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: From an ad hoc international expert panel. *Blood* 110:1092, 2007.
*Hemoglobin or hematocrit >99th percentile of method-specific reference range for age, sex, altitude of residence, *or* hemoglobin >17 g/dL in men and 15 g/dL in women if associated with a documented and sustained increase of at least 2 g/dL from an individual's baseline value that cannot be attributed to correction of iron deficiency, *or* elevated red blood cell mass >25% above mean normal predicted value.

dasatinib, and nilotinib. With the distinctive cytogenetic abnormalities and molecular genetic abnormalities that are unique to CML (Philadelphia chromosome, *BCR-ABL* gene fusion), these two disorders should not be difficult to differentiate. Occasional patients with an MPN have been shown to have both JAK2V617F as well as *BCR-ABL;* whether this unusual occurrence takes place in two different clones and thereby represents two independent MPNs or a single clone and is caused by the predisposition of such patients to acquire mutations in their hematopoietic cells is a subject of speculation. This association has been reported in about 2% of CML patients with the CML disease phenotype predominating in most.

Patients with PMF can present with abnormalities that are virtually indistinguishable from those of patients with PV-related MF. Almost 50% of PMF are JAK2V617F positive, but more than 90% of patients with post-PV MF are JAK2V617F positive. The survival of patients with the latter disorder is much shorter than that of patients with the former condition. Some patients with presumed PMF may actually develop PV after the institution of chemotherapy.

A preceding history of PV permits differentiation between these two situations. ET and PV with marked thrombocytosis can easily be confused. When the RBC mass is used as a definitive diagnostic test, a distinction between ET and the erythrocytotic phase of PV is usually readily apparent. This measurement, however, can be normal or actually low in patients with PV who are iron deficient because of bleeding or excessive phlebotomy. Campbell and coworkers[25] have recently used sensitive PCR-based methods to assess the JAK2 mutational states in 806 patients with ET. The mutation was present in more than 50% of patients with ET. JAK2V617F-positive ET patients were characterized by multiple features that resembled those of patients with PV, including higher hemoglobin levels, higher WBC counts, more prominent BM erythroid and granulocytic hyperplasia, a higher incidence of venous but not arterial thrombosis, low serum EPO levels, and lower serum ferritin levels. Surprisingly, JAK2V617F-negative patients had higher platelet counts. Furthermore, JAK2V617F-positive ET patients had a higher probability of developing PV with longer follow-up. Acquisition of homozygosity for the JAK2V617 caused by homologous recombination is likely the critical event in the development of PV in JAK2V617F ET patients. Homozygosity for JAK2V617F occurs in at least 30% of patients with PV but is extremely rare in ET.

PROGNOSIS

The prognosis of a patient with PV depends on the nature and severity of the complications that occur during the clinical course of that particular patient's disorder. In addition, an individual patient's prognosis depends on the duration of the erythrocytotic phase or the time to transition to post-PV MF or acute leukemia. Survival is also influenced by whether appropriate treatment is instituted during the erythrocytotic phase of the illness. Patients who have uncontrolled erythrocytosis are at an extremely high risk for the development of thromboses. The median survival time from the onset of symptoms has been reported in a study that is over 4 decades old to be as short as 1.5 years in untreated patients, but this number seems excessive because of the relatively large number of patients who are diagnosed during routine examinations and are asymptomatic for prolonged periods of time. Determination of the optimal management of patients with PV has been a difficult task because the disease, when treated, is associated with a survival period of approximately 17 years. Studies of new potential therapeutic interventions therefore require prospective studies with prolonged follow-up times before meaningful results can be generated determining their ability to improve upon overall survival.

Increasing age and history of vascular events have consistently proven to be independent predictors of developing additional thromboses in patients with PV. In the ECLAP trial, the incidence of cardiovascular complications was higher in patients older than 69 years of age, patients with a history of thrombosis, and patients with WBC counts higher than 15,000 × 109 L^{-1}. Conventional cardiovascular risk factors, including hypertension, hyperlipidemia, diabetes, and smoking, are assumed to be associated with the same relative risk of developing thrombosis in PV patients as that observed in the general population. Although practicing hematologists are frequently concerned about elevated platelet counts in PV patients, several reports have failed to show any association between platelet count and thrombotic events, suggesting that therapies in PV targeting reduction of platelet numbers are ill conceived.

Table 67-5 Risk Stratification in Polycythemia Vera Based on Thrombotic Risk

Risk Category	Age >60 Years or History of Thrombosis	Cardiovascular Risk Factors*
Low	No	No
Intermediate	No	Yes
High	Yes	

Data from Finazzi G, Barbui T: How I treat patients with polycythemia vera. *Blood* 109:5104, 2007.
*Hypertension, hypercholesterolemia, diabetes, and smoking (see text).
Extreme thrombocytosis (platelet count >1500 × 10^9 L^{-1}) is a risk factor for bleeding. Its role as a risk factor for thrombosis is uncertain. An increasing leukocyte count has been identified as a novel risk factor for thrombosis, but confirmation is required.

These data have led to stratification of therapy in patients with PV based on clearly identifiable risk factors (Table 67-5) of developing additional thrombotic events. The development of acute leukemia was a relatively rare event in PV, occurring in 22 of 1638 patients in the ECLAP observational study after a median of 8.4 years from the time of diagnosis. Older age as well as treatment with P^{32}, busulphan, and pipobroman was associated with a four- to eightfold increased risk of developing AML of an MDS compared with patients treated with phlebotomy alone, hydroxyurea, or INF. For reasons not presently understood, patients presenting with PV and low blood cholesterol levels are at an especially high risk for developing acute leukemia.

Recently, the effect of JAK2V617F allele frequency on the prognosis of PV patients has been examined. More than 95% of patients with PV are JAK2V617F positive, and their mutational load can be determined by allele-specific PCR. Approximately 30% of PV patients have a high JAK2V617F burden (>50%), and the remainder have a lower burden (<50%), with the small numbers being wild type. Some investigators, but not all, have reported that high burdens of JAK2V617F in PV patients are associated with larger splenic volumes, more frequent aquagenic pruritus, a higher incidence of thrombotic events, and a higher rate of evolution into MF and acute leukemia.

High leukocyte counts (>15,000 × 10^9/L) at the time of diagnosis has been identified as another independent predictor of developing a major thrombosis in PV patients. In addition, others have suggested that this parameter is predictive of evolution to MF and an overall inferior survival time.

The choice of therapeutic agents used to treat the erythrocytotic phase of disease clearly influences patient outcomes. The use of alkylating agents and radioactive phosphorous is associated with an established risk for leukemic transformation or evolution to MDS. Clearly, this risk is also associated with increased duration of the disease. The effect of hydroxyurea on leukemic transformation rates is an area of controversy. In addition, the influence of long-term INF therapy on disease outcomes is not at present clearly defined.

THERAPY

A cumulative duration of survival for PV patients treated with modern strategies of between 15 and 17 years has been reported. Despite the implementation of standard therapeutic strategies, the

mortality rate of PV patients is increased by 1.84 compared with age- and sex-matched populations. At present, the goals of therapy are directed toward normalization of blood counts in an attempt to avoid additional thrombotic events. Therapy is also stratified based on the presumed risk of an individual patient to develop additional thrombotic episodes, with low-risk patients being treated with phlebotomy therapy alone plus a therapy directed toward paralysis of platelet function and high-risk patients receiving not only phlebotomy plus antiplatelet therapy but also some form of myelosuppressive therapy (hydroxyurea, INF, anagrelide, busulfan). At present, the therapeutic goals are to reduce the risk of thrombosis by normalizing the hematocrit levels to 45% or lower in males and 42% or lower in females, but the relationship between maintaining hematocrit levels under target values and clinically relevant outcomes remains the subject of much spirited speculation rather than being based on a firm foundation of evidence. In a retrospective analysis, Spanish investigators reported that maintaining the hematocrit below 45% was not associated with a decreased thrombotic risk. These data should not be interpreted to mean that phlebotomy therapy for excessive erythrocytosis should be abandoned, but rather that the need to maintain patients below hematocrits of 45% likely does not provide any advantage. Previous studies have indicated a lack of a relationship between thrombocytosis at diagnosis or during the period of follow-up with thrombotic complications, yet in the Spanish study, there was an association between lack of reduction of platelet numbers below 400×10^9/L and an increased risk of thrombosis, and that persistence of leukocytosis was associated with a greater risk of hematologic transformation and shorter survival time but not a reduced incidence of thrombosis. Whether therapy should be directed at normalization of platelet or leukocyte numbers is unclear. Phlebotomy therapy alone is the standard of care for low-risk PV patients. Several investigators have, however, suggested that patients have serious nonhematologic symptoms secondary to the iron deficiency that inevitably accompanies repeated phlebotomies. A careful evaluation of symptoms fails to provide convincing evidence that undue fatigue occurs as a result of iron deficiency in PV patients with normal or elevated hematocrit values. Phebotomized PV patients do not experience dysphagia or the esophageal changes associated with chronic iron deficiency. The two symptoms that have been observed to occur regularly are picophagia, a pica consisting of compulsive ice eating, and restless leg syndrome. These symptoms can be resolved with ingestion of extremely small amounts of oral iron, which might increase the need for phlebotomy therapy (see box on General Principles of Therapy).

A series of studies, although completed more than 30 years ago, by the Polycythemia Vera Study Group has answered several very important questions regarding the efficacy and associated complications of particular therapeutic modalities. These investigations have aided in the identification of optimal therapy for individual patients, which must be selected on the basis of age and comorbid disease status to minimize treatment-related complications.

The first PVSG randomized trial (01 trial) evaluated three treatment strategies: (1) phlebotomy alone to maintain the hematocrit level at less than 45%; (2) intravenous ^{32}P, 2.3 mCi/m^2 repeated every 12 weeks, if needed (maximum, 5 mCi per dose) supplemented by phlebotomy to maintain the hematocrit level at less than 45%; and (3) myelosuppression with chlorambucil 10 mg/day orally for 6 weeks and then daily on alternate months with necessary dose reductions and supplemental phlebotomy. More than 400 patients were randomly assigned to this protocol. The median survival duration from entry into the study until death was 9.1 years for patients treated with chlorambucil, 10.9 years for those treated with ^{32}P, and 12.6 years for the phlebotomy group. Long-term survival was inferior for patients treated with chlorambucil compared with those treated with ^{32}P or phlebotomy. An early finding was the appearance during the first 5 years of a significant excess of deaths from acute leukemia in the chlorambucil arm, which reached 17% after 15 years of follow-up. As a result, the chlorambucil arm was discontinued, and patients were assigned randomly to one of the other two arms. Even though no statistical difference in overall survival between ^{32}P and phlebotomy alone was apparent through the first 10 years, the morbidity and mortality associated with each type of therapy were attributable to distinctly different causes. Thrombosis as a cause of death was much more frequent in the phlebotomy-only group during the first 5 to 7 years of follow-up. Analyses of factors associated with thrombosis revealed that the performance of phlebotomy, the rate of phlebotomy, advancing age, and history of previous thrombosis were statistically significant factors predictive of this outcome. In contrast, the use of ^{32}P led to a lower rate of thrombosis during the first 5 years, but the incidences of leukemias, lymphomas, and nonhematologic malignancies increased during the next 5 years to nearly 10%. After a 15-year period of observation, the incidences of leukemia and lymphoma in the chlorambucil group had risen to 17%. A statistically significant increase in skin and gastrointestinal cancers occurred in the ^{32}P- and chlorambucil-treated cohorts compared with the group treated with phlebotomy alone (see box on Algorithm for Management of Patients With Polycythemia Vera).

General Principles of Therapy

1. The etiology of erythrocytosis must be correctly categorized to be certain the patient has PV. This will avoid inappropriate exposure of patients with nonmalignant disorders to potential leukemogenic agents. To this end, a major contribution is played by incorporating a JAK2V617F and exon 12 JAK2 mutational determinations in the diagnostic workup, and in this way, early phases of PV can be recognized as well. In individuals with erythrocytosis without a JAK2 mutation, search for mutations in VHL, PHD2, HIF-1 and HIF-2 should be considered.
2. Therapy should be individualized.
3. Initially, the hematocrit should be reduced to 45% as soon as possible. The speed of phlebotomy will depend on patients' general medical conditions (250-500 mL every other day). Elderly patients with compromised cardiovascular or pulmonary systems should be more carefully phlebotomized (twice a week), or smaller volumes of blood should be removed.
4. Hematocrit levels should be maintained at 45%.
5. The use of chemotherapeutic agents should be avoided in low-risk PV patients, and treatment with hydroxyurea or INF should be reserved for high-risk patients. Be on the look-out for toxicities from each of these agents.
6. Hyperuricemia is treated with allopurinol (100-300 mg/day).
7. Pruritus is treated empirically with cyproheptadine 4 to 16 mg/day or, if unsuccessful, INF-α therapy 3.0×10^6 units subcutaneously three times a week. A role of selective serotonin uptake inhibitors (paroxetine 20 mg/day or fluoxetine 10 mg/day) or with phototherapy has been proposed. Dramatic relief occurs with the institution of JAK2 inhibitors, and these agents should be used as a component of an experimental trial or if the patients have features that justify the diagnosis of post-PV MF syndrome.
8. Elective surgery or dental procedures should be delayed until hematocrit and platelet counts have been normalized for more than 2 months. Aspirin should be withdrawn at least 1 week before surgery. If emergency surgery is contemplated, phlebotomy and cytapheresis should be pursued.
9. Women and men who are contemplating having children should be treated by phlebotomy plus low-dose aspirin therapy (81 mg/day or with INF-α) to avoid teratogenic effects of chemotherapy. Such avoidance will also prevent deleterious effects on fertility. During pregnancy, therapy is frequently not necessary; if it is, phlebotomy plus low-dose aspirin should be exclusively used. If phlebotomy control is inadequate, treatment with INF-α should be pursued.

Algorithm for Management of Patients With Polycythemia Vera

Low-risk young patients (age <60 years) and no history of thrombosis, platelet count <1.5 × 10⁶ mm⁻³

Phlebotomy + low-dose aspirin (81 mg/day) to maintain hematocrit lower than 45% in males and lower than 42% in females. Aspirin should not be used in patients with histories of a hemorrhagic episode or with extreme thrombocytosis (>1.5×10^6 mm^{-3}) or acquired von Willebrand syndrome.

↓

Thrombosis or hemorrhage
Systemic symptoms
Severe pruritus refractory to histamine antagonists
Painful splenomegaly

↓

Hydroxyurea 15-20 mg/kg (unless younger than 40 years, pregnant, intolerant to hydroxyurea; consider pegylated INF)

↓

Pegylated INF 45 to 180 µg/wk or INF - (3×10^6 units three times a week; alter dose depending on response and toxicity). Consider the use of pegylated INF, which can be administered once weekly.

↓

If platelet control is inadequate or patient cannot tolerate interferon, one option is the use of anagrelide. However, the use of this drug is controversial. In this case, supplemental phlebotomy is required to maintain hematocrit lower than 45% in males and lower than 42% in females, and the use of hydroxyurea should be considered, especially if patient continues to have thrombotic episodes.

↓

If the patient has increasing splenomegaly, systemic symptoms, or repeated thromboses despite adequate dose of hydroxyurea (2-3 g/day), start busulphan, 4 to 6 mg/day orally for 4 to 8 weeks. It should be mentioned that the sequential use of hydroxyurea and busulphan may be associated with an increased risk of leukemia. Supplemental phlebotomy may be required.

Painful splenomegaly

↓

Splenectomy + continued systemic therapy

↓

High-risk patients (age >60 years), previous thrombosis, platelet count >1.5 × 10⁶ mm⁻³

Phlebotomy to hematocrit of 42% in females and 45% in males

Aspirin (81 mg/day) to be given only in patients with platelet counts <1.5×10^6 mm^{-2}

Myelosuppressive therapy with hydroxyurea 30 mg/kg orally for 1 week

Then 15 to 20 mg/kg

↓

If patient continues to have thrombotic episodes and has extreme thrombocytosis or cannot tolerate hydroxyurea

Consider pegylated INF 45 to 180 µg/wk or add busulphan 4-6 mg/d orally for 4 to 8 weeks.

If on bisulphan, stop when blood counts are normalized or platelet count is lower than 300,000 mm^{-3}.

Occasional supplemental phlebotomy if hematocrit is >42% in females and greater than 45% in males; when patient relapses (patient is symptomatic), initiate busulphan therapy again at same dose.

Patient age >70 years

Phlebotomy + low-dose aspirin + hydroxyurea

↓

No response or poor compliance

Busulphan 4 to 6 mg/day orally for 4 to 8 weeks. Stop when blood counts are normalized or platelet count is lower than 300,000 mm^{-3}.

Given the paradox of equal 10-year survivals but demise because of distinct causes in comparable populations of patients treated by phlebotomy alone or by phlebotomy plus ^{32}P, the PVSG pursued strategies to reduce the thrombotic risk in the phlebotomy-only group. One study attempted reduction of the thrombotic risk by combination antiplatelet therapy. It appeared possible that therapy directed toward altering platelet function might reduce the frequency of thrombosis. Therefore, a randomized trial was performed in which phlebotomy, supplemented with the platelet antiaggregating agents aspirin and dipyridamole, was compared with ^{32}P (PVSG trial 05). The outcome for the group treated with phlebotomy, aspirin, and dipyridamole was disappointingly inferior to the ^{32}P results. In fact, more thromboses occurred in the former than in the latter group, but surprisingly, there was also a significantly greater incidence of severe gastrointestinal hemorrhages.

Renewed impetus for the use of nonchemotherapeutic agents for the treatment of PV was provided by an extensive natural history study of 1213 patients reported by the Gruppo Italiano Studio Policitemia. They showed that the age- and gender-standardized mortality rate of patients with PV was 1.7 times greater than the mortality rate of control participants in the general Italian population. In addition, four times as many patients who had previously received ^{32}P, alkylating agents, or hydroxyurea died of cancer compared with patients treated with phlebotomy alone. When this group combined the total number of deaths and the number of nonfatal myocardial infarctions and strokes, they found an unsatisfactory risk-to-benefit profile in patients treated with chemotherapeutic agents and suggested that antithrombotic strategies, such as low-dose aspirin, be carefully evaluated for use in the care of patients with PV.

In light of more recent knowledge of the dose requirements for selective antiplatelet therapy with aspirin, it appears that the PVSG study of platelet antiaggregating agents might have failed because of the use of excessive aspirin dosages (900 mg/day). Such aspirin doses appear to diminish vascular endothelial production of the platelet antiaggregatory factor, prostacyclin I_2 (PGI_2).

Polycythemia vera platelets are known to have a generalized abnormality of arachidonate metabolism that is characterized by enhanced synthesis of thromboxane A_2, which likely reflects stimuli to platelet activation. The exact mechanism responsible for enhanced platelet synthesis of thromboxane A_2 in PV remains unknown and requires further investigation. A low-dose aspirin regimen (50 mg/day for 7-14 days) has been shown to suppress more than 80% of the excretion of the metabolites of thromboxane A_2. A pilot study was performed in which the toxicity of low-dose aspirin therapy in PV patients was evaluated. A very-low-dose aspirin regimen (40 mg/day) was chosen to prevent thrombosis yet minimize the risk of bleeding. After follow-up of the low-dose aspirin treatment group and control group, low-dose therapy was shown not to be associated with an increased incidence of bleeding complications. Aspirin therapy was well tolerated and was associated with complete inhibition of platelet cyclooxygenase activity. A large, randomized, placebo-controlled clinical trial testing the risk-to-benefit ratio of low-dose aspirin therapy in preventing thrombotic episodes in PV has been completed. Treatment with low-dose aspirin (100 mg/day) compared with placebo reduced the risk of the combined end points of nonfatal myocardial infarction, nonfatal stroke, pulmonary embolism, major venous thrombosis, or death from cardiovascular courses. Overall mortality and cardiovascular mortality, however, was not reduced significantly by aspirin therapy. Importantly, the incidence of major bleeding episodes was not significantly increased in the aspirin group. It is important to emphasize that patients require aggressive phlebotomy therapy to the appropriate target hematocrit levels as well as the appropriate use of myelosuppressive agents as primary therapy, with the addition of aspirin serving as an adjunct to this strategy. The conclusions of this study have been questioned by several investigators. In addition, a retrospective analysis performed by independent investigators of the 630 patients treated by the ECLAP group has concluded that low-dose aspirin therapy in PV patients was associated with a statistically nonsignificant reduction in the risk of fatal thrombotic episodes without an increased risk of bleeding.[26] This

meta-analysis is surely not a ringing endorsement of the widespread use of aspirin therapy, which is a strategy that has been indiscriminately used worldwide to treat such patients. Because it is unlikely that the value of aspirin therapy will be examined in a properly powered randomized trial, it is suggested that since aspirin therapy is a relatively innocuous therapy it should be used in high-risk patients judiciously. However, it should be avoided in patients with extremely high platelet counts who are at risk for hemorrhage. There is no evidence at present to indicate the necessity of its use in patients with low-risk disease.

It is interesting to compare the results of the PVSG study with those of a randomized trial of ^{32}P versus busulphan for the treatment of PV conducted by the European Organization for Research and Treatment of Cancer (EORTC). The two studies were comparable in size, design, and duration of follow-up. In the EORTC trial, induction courses of busulphan 4 to 6 mg/day for 4 to 8 weeks were compared with ^{32}P treatment. Patients treated with busulphan had a survival advantage over ^{32}P-treated patients. This difference was due primarily to a threefold greater incidence of fatal thrombotic events in the ^{32}P group. Interestingly, the incidence of leukemia in both groups was very low (<2%), with an overall malignancy rate of less than 10% (involving mostly solid tumors).

It is reasonable to conclude from this trial that busulphan is a myelosuppressive agent with limited leukemogenic potential when used on an intermittent schedule. A retrospective study of patients in England treated with phlebotomy and intermittent busulphan supports these same conclusions.

After the disappointing results experienced with the alkylating agent chlorambucil, the PVSG began a nonrandomized phase II investigation of hydroxyurea, an S-phase–specific ribonucleotide reductase inhibitor. The hope was that this agent would be nonleukemogenic. Of 53 patients with PV treated with hydroxyurea who had never received other forms of myelosuppression, after follow-up for a median period of 8.6 years and a maximum follow-up of 795 weeks, 5.4% developed acute leukemia compared with 1.5% of patients treated with phlebotomy alone on the original PVSG randomized study.

In a comparable trial from Israel 71 patients were treated with hydroxyurea for a mean duration of 7.3 years. Remarkably, the incidence of thrombosis was only 6%, indicating the impressive potential of hydroxyurea to lower the incidence of thrombosis in patients with PV, confirming an observation previously made by another group. The incidence of leukemia in the Israeli trial was 5.6%. In another retrospective series, the incidence of acute leukemia and myelodysplasia in patients with PV treatment of hydroxyurea alone was 6.9%. In patients treated first with busulphan and then hydroxyurea, the rate of acute leukemia and myelodysplasia was 13.8%. Twenty-two patients developed AML and MDS in the ECLAP study that enrolled 1638 patients. AML and MDS were diagnosed after a median of 8.4 years from the diagnosis of PV; the variable associated with progression was older age, but overall disease duration (>10 years) failed to reach statistical significance. Exposure to P^{32}, busulphan, and pipobroman but not hydroxyurea alone had an independent role in producing an excess risk for progression to AML and MDS compared with treatment with phlebotomy or INF. The potential leukemia-promoting potential of hydroxyurea has been readdressed in two recent studies. Kiladjian and coworkers[22] reported the results of a randomized trial of hydroxyurea versus piprobroman that was initiated in 1980; the overall survival was 20.3 years in the hydroxyurea-treated group compared with 15.4 years for the patients treated with piprobroman. The incidence of AML and MDs in the piprobroman group was dramatically higher, which is not unexpected because pipribroman is an alkylating agent. This trial was designed with a cross-over option, but 93 patients only received piprobroman. The incidence of AML and MDS in the patient group that only received hydroxyurea was 7.3%, 10.7%, and 16.6% at 10, 15, and 20 years, respectively. Such high rates of transformation have not been previously reported, and because there was not a control arm treated with phlebotomy alone, one cannot determine if this represents the natural history of PV or a potential leukemogenic effect of hydroxyurea. Interestingly, no difference in the incidence of vascular events was seen between the two arms. This same question was again addressed in a nested case control study performed in Sweden.[27] The most important observation was that 25% of patients with various MPNS (68% had PV) who evolved to AML and MDS had not been exposed to any chemotherapeutic agent, indicating that the risk of leukemic evolution was higher than had been previously appreciated. The use of radioactive phosphorous and alkylating agents, but not hydroxyurea, was associated with a higher rate of AML and MDS. These reports indicate that nontreatment-related factors play a major role in the development of AML and MDS, and the contribution of hydroxyurea based on the best available evidence is at best minimal, but likely not totally without risk. However, the documented ability of hydroxyurea to lower the incidence of thrombotic events and its very limited leukemogenic potential makes this drug a very useful chemotherapeutic agent in older, high-risk patients with disease that cannot be controlled with phlebotomy alone. Excessive myelosuppression, macrocytosis, hypersegmentation of polymorphonuclear leukocytes, cutaneous actinic keratosis, squamous cell carcinoma of the skin, hyperpigmentation, stomatitis, painful leg ulcers, creatinine elevations, and jaundice have been attributed to the use of hydroxyurea. Aphthous and leg ulcers occur in 9% of patients, usually after approximately 10 months of therapy (see Fig. 67-12).[28] Rarely, cycling of platelet and leukocyte counts but not RBCs occurs while patients are being treated with hydroxyurea. In this situation, the authors have maintained patients on a fixed dose of hydroxyurea rather than chasing cycling platelet counts. In addition, the use of hydroxyurea requires patient compliance and careful monitoring of blood counts to avoid the sequelae of excessive myelosuppression.

Some clinical investigators have suggested that a program of phlebotomy alone would be the most appropriate for younger patients, who have not experienced a cerebrovascular or cardiovascular event. Strong consideration should be given to the use of phlebotomy therapy in conjunction with low-dose aspirin therapy in addition to the use of such apparently nonleukemogenic drugs as INF-α in this younger patient population.

Anagrelide, a selective inhibitor of platelet production, has been used to treat thrombocytosis in PV patients with thrombotic or hemorrhagic complications. This agent appears to be nonleukemogenic and acts by impairing megakaryocyte maturation. Its use leads to a selective reduction in platelet numbers, and it has been effective in patients refractory to hydroxyurea and INF. This drug does not effectively control the erythrocytosis and leukocytosis or systemic symptoms associated with PV and therefore was suggested to be used as a supplement to phlebotomy therapy. The time to complete response generally ranges between 17 and 25 days. The dose of anagrelide required to control thrombocytosis remains constant over time in most patients. When anagrelide is discontinued, platelet counts returned to pretreatment levels within 5 to 7 days. The simultaneous administration of anagrelide and low-dose aspirin has been

Figure 67-12 EXAMPLE OF A HYDROXYUREA-INDUCED LEG ULCER. *(From Soutou B, Aractingi S: Myeloproliferative disorder therapy: Assessment and management of adverse events: A dermatologist's perspective.* Hematol Oncol *27:11, 2009.)*

reported to lead to a significant increase of bleeding manifestations. Clinicians presume that the effects of anagrelide observed in ET patients will be relevant to patients with PV. This assumption has not been tested in a randomized clinical trial. Anagrelide therapy should be reserved for patients with recent thromboses (e.g., myocardial infarction, stroke, migraines, erythromelalgia) and with thrombocytosis that cannot be controlled with INF or hydroxyurea therapy alone. It can also be used in combination with hydroxyurea to minimize adverse events that accompany the use of each drug alone. Anagrelide should not be used in pregnant patients because it can easily cross the placenta, leading to adverse effects on the platelet count of the fetus.

Approximately 15% to 20% of patients treated with anagrelide discontinue the medication because of nonmyelosuppressive side effects. The spectrum of adverse effects involved neurologic (headaches and dizziness), cardiac (vasodilatation, fluid retention, congestive heart failure, palpitations, and tachycardia), and gastrointestinal (nausea) toxicities. These toxicities reflect the novel mechanism of action of anagrelide as a cyclic nucleotide phosphodiesterase inhibitor. Anagrelide should be used with caution in patients with known or suspected cardiac disease because of its ability to promote fluid retention. Because many patients with PV are elderly, careful attention to fluid status should be maintained to avoid slipping into congestive heart failure after the initiation of anagrelide.

Interferon-α therapy has been explored for several decades for the treatment of PV patients, but its positive effects have been more greatly appreciated during the past 5 to 7 years.[29] Its effects on myeloid malignancies are likely the consequence of its broad range of biologic activities, including direct effects on malignant cells, enhancement of antitumor immune responses, induction of proapoptotic genes, inhibition of angiogenesis, and promotion of the cycling of dormant malignant stem cells. Because of the recent development of "targeted" therapies, the use of IFN has been dramatically reduced over the past decade. The increasing awareness of the multistep pathogenesis of many malignancies has suggested, however, that such an approach using target-specific agents is not universally effective. This awareness provided the rationale for the use of an agent such as INF-α that might be especially useful for the treatment of a disease in which multiple genetic, epigenetic and environmental factors contribute to its origin and progression. INF-α promotes apoptosis of a variety of tumor cell types. The induction of apoptosis by INF-α involves the activation of a number of INF-stimulated genes that mediate this response. Gene expression studies have identified more than 15 INF stimulated genes with proapoptotic functions. Although these INF-stimulated genes alone are probably not sufficient to induce apoptosis, their cumulative effects likely result in apoptosis. These mediators of apoptosis include caspase 4, caspase 8, TNF-related apoptosis-inducing ligand (TRAIL), Fas/CD95, the X-linked inhibitor of apoptosis (XIAP), death-activating protein kinases, INF regulatory factors, dsRNA-activated protein kinase, and *PML* (acute promyelocytic leukemia gene). The induction of caspase 8 and caspase 4 by INF may sensitize tumor cells to death receptor (TRAIL and Fas L)–mediated apoptosis. The ability of INF to induce apoptosis is independent of cell-cycle arrest, the presence of wild-type p53, or expression of Bcl-2 family members but appears to always involve the FAS-associated death domain (FADD)/caspase 8 signaling, activation of the caspase cascade, which leads to disruption of mitochondrial potential and eventual DNA fragmentation. Conflicting evidence exists as to the role that STAT1 and STAT2 play in INF-induced apoptosis. It appears most likely that the PI3K and JAK–STAT pathways act independently of each other in mediating INF-α–induced apoptosis and that the particular pathway operating is dependent on the target cell type. Several of these pathways may actually act together to contribute to IFN-α–induced apoptosis of tumor cells. Type 1 IFNs suppress the ability of normal human HPCs to proliferate in vitro in the presence of cytokine combinations. IFN-α acts directly against HPCs; this inhibitory activity has been documented using $CD34^+$ cell populations. This inhibitory role of IFN-α has been shown to synergize with the inhibitory activities of IFN-γ, which is likely produced by BM auxiliary cells in response to IFN-α. PV $CD34^+$ cells are more sensitive to the inhibitory effects of IFN-α than normal HPCs. The myelosuppressive effects of IFN-α can also be partly attributed to the inhibition of the paracrine production of several stimulatory hematopoietic growth factors, including GM-CSF and IL-11, and inhibition of the production of IL-1 receptor antagonist by BM stromal cells. INF-α therapy of hepatitis patients is frequently complicated by dose-limiting thrombocytopenia. This has led to a more careful examination of the effects of INF-α on normal megakaryocyte development. This cytokine directly inhibits megakaryocyte HPC proliferation and differentiation by blunting the JAK–STAT signaling responses that occur in response to TPO and impairs TPO-induced intracellular signaling by upregulating SOCS-1 expression. INF-α reduces TPO-induced activation of MPL, as well as phosphorylation of JAK2, JAK3, and STAT5. Furthermore, INF-α directly inhibits cytoplasmic maturation and platelet production by megakaryocytes but not the proliferation of megakaryocyte progenitor cells or endomitosis of human megakaryocytes.

The ability of type 1 INFs to inhibit HPC proliferation and maturation has been documented to occur independently of the STAT pathway. Type 1 INFs activate the p38 MAPK, a proline-directed serine/threonine kinase that is required for INF-stimulated gene transcription through interferon sensitive response element (IRSE). The pharmacologic blockade of p38 in IFN-treated PV HPCs reverses the inhibitory effects of INF-α. The inhibitory activities of type 1 INF against normal and malignant HPCs involve several additional downstream signaling pathways, including the Crkl adaptor protein, the MAPK-interacting kinase 1 (Mnk), a MAPK-regulated kinase that phosphorylates the eukaryotic initiation factor 4e, and the Schlafen family of proteins that includes several members that regulate cell-cycle progression and growth arrest. The relative contribution of each of these pathways to the antiproliferative effects of INF-α on HPCs requires further investigation. P38 MAP kinase activation by INF-α has been reported to promote apoptosis of PV $CD34^+$ cells. Activation of p38 MAP kinase results in mitochondrial translocation of the proapoptotic protein Bax, leading to the induction of apoptosis.

Interferon has also been shown to be able to affect HSC behavior. High levels of INF-α induce murine HSCs to exit from a normally quiescent state and to transiently proliferate. In these studies, the HSC proliferative response was not observed in HSCs that lacked the INF receptor or STAT1. However, HSCs that lacked the INF receptor did respond to INF-α if they were mixed with wild-type cells, suggesting that other cytokines such as INF-γ that are elaborated by BM auxiliary cells may be responsible for this biologic activity. In support of this hypothesis is the recent report that IFN-γ is also capable of inducing HSC cycling. The effect of IFNs on HSC cycling appears to occur by a pathway that is distinct from the pathway which mediates their antiproliferative effect on HPC. STAT1 is required for the IFN-α–mediated exit of HSC from dormancy, suggesting that this effect is mediated by canonical type 1 IFN signaling. It remains uncertain whether human HSCs respond in a similar fashion to IFN-α, and clonal stem cells from MPN patients cycle at a higher rate than the small reservoir of normal HSCs that persist in such patients.

In the United States, the pioneering study of Silver[30] in 1988 documented the clinical effectiveness of IFN-α in controlling erythrocytosis as well as pruritus and other constitutional symptoms in PV patients, and Austrian and French groups reported during the same period evidence that IFN-α was also effective in reducing thrombocytosis in ET patients. A number of clinical trials have been performed subsequently using several different commercial preparations of IFN. Recent reviews of the literature found more than 400 PV and ET patients who participated in clinical trials. A meta-analysis of these studies has proven problematic. First, various forms of IFN were used, and one cannot exclude the possibility that each of these preparations of IFN might have different effects that might influence response rates or disease evolution. Furthermore, heterogeneous response criteria were used to evaluate efficacy. The recently proposed response criteria for use in MPNs clinical trials provided by the European LeukemiaNet might be helpful to avoid such a dilemma

in the future. In almost all PV and ET trials, IFN-α therapy rapidly normalized platelet numbers and corrected the degree of leukocytosis and erythrocytosis, allowing reduction in the requirement for phlebotomies within a few months. In both diseases, an objective hematologic response was observed in about 80% of patients, including complete freedom from phlebotomies in PV in 60% of patients. In addition, IFN-α was also able to reduce PV-associated pruritus in a significant number of patients and appears to be an effective drug for this purpose. However, toxicity associated with IFN-α therapy was not trivial, leading to the discontinuation of treatment in almost 25% of patients. A pegylated form of INF has been used with increasing frequency to treat patients with a variety of MPNs with great success. This form of INF can be administered once weekly, and its use is associated with a more favorable toxicity profile. Several phase 2 studies using peg-IFNα-2a in PV and ET showed similarly impressive hematologic response rates compared with standard IFN-α but with less associated toxicity (<10% of patients discontinued therapy during the first year of therapy). In addition, these studies showed for the first time evidence of significant molecular responses as documented by a clear reduction in the JAK2V617F allele burden after IFN-α treatment.[30] A specific effect of IFN-α against the MPN clone had previously been suggested by occasional studies showing reversion from monoclonal to polyclonal patterns of hematopoiesis (based on X chromosome inactivation pattern studies) or disappearance of a marker chromosomal abnormality present before treatment. The discovery of the JAK2V617F mutation provides a tool with which to measure molecular response to a variety of therapeutic approaches in MPN, an end point not available before the discovery of this mutation in 2005. Overall, the two clinical trials with peg-IFNα-2a showed a meaningful and progressive reduction in the JAK2V617F allele burden in about 70% of PV and 40% of ET patients. Importantly, the JAK2V617F mutation became undetectable (with 1% sensitivity PCR assays) in 24% of PV patients in the French "PVN-1" study after about 3 years' median follow-up, and in 14% and 6% of PV and ET patients, respectively, in the U.S. study after about 2 years' median follow-up. Combining both studies, 12 of 64 (19%) PV patients achieved a molecular complete response (MCR). Of note, each of these MCRs occurred after the 12th month of treatment, but hematologic responses occurred within a few weeks. Prolonged exposure (>12 months) to peg-IFNα-2a seems to be an important factor in achieving MCR. The reduction in the JAK2V617F allele burden was not influenced by the cumulative dose of peg-IFNα-2a in the PVN-1 study, but toxicity was clearly dose dependent in the U.S. study. Taken together, these results indicate that peg-IFNα-2a therapy is best initiated at very low doses that are gradually increased until hematologic response is achieved; this strategy avoids cessation of therapy and allows sufficient exposure to the drug to allow for the achievement of a molecular response. These results are in agreement with studies from Denmark, showing major molecular responses in PV after long-term treatment with IFNα-2b that could persist after IFN-α was discontinued. Finally, five of seven patients who achieved MCR in the PVN-1 study have maintained this response after peg-IFNα-2a was discontinued (≤30 months after discontinuation), with none experiencing hematologic relapse. Such long-term clinical and molecular responses after the discontinuation of treatment have previously been reported after IFN-α therapy in MPN patients, an effect that has not been reported with other currently available therapies. It is important to emphasize that the elimination of JAK2V617F in this setting is not necessarily indicative of cure of the MPN and that clinical implications of these molecular responses remain uncertain and require validation. It has been shown that molecular relapse can rapidly occur after IFN-α discontinuation in some cases. In one patient with a biclonal JAK2V617F/TET2-mutated PV, peg-IFNα-2a treatment did not affect the TET2-mutated cells, but the JAK2V617F clone was eradicated. Nevertheless, prolonged periods of time (≤40 months, personal unpublished data) during which the patient remained in complete hematologic remission without any cytoreductive therapy after peg-IFNα-2a withdrawal was observed in several patients of the PVN-1 study even though low levels of the JAK2V617F allele (≈5%) were still detected. Such results suggests that despite the disease not being eradicated, long-term exposure to peg-IFNα-2a was sufficient to modify the clinical expression of the MPN for a sustained period of time.

In addition to clinical, hematologic, and MCRs achieved in a significant proportion of PV and ET patients, IFN-α therapy has also been shown recently to reverse BM histopathologic abnormalities in selected cases of both PV and PMF. Thus IFN-α seems to be the uniquely available drug able to induce complete resolution of all clinical, biologic, and morphologic abnormalities in selected MPN patients, raising the hope that a curative outcome might be possible in a subset of such patients. These observations lead one to question the validity of the current therapeutic strategies for PV and ET patients in which myelosuppressive therapy is exclusively used in subpopulations of patients at high risk for developing additional thrombotic events. If IFN-α is shown in a large prospective trial to eliminate clinical, histologic, cytogenetic, and molecular evidence of disease with acceptable toxicity, one might also consider early treatment of low-risk patients when the tumor burden is still low.

Intolerance to therapy with INF-α leads to drug withdrawal in 14% of patients. INF is not a leukemogenic drug but it is not an innocuous agent, necessitating careful follow-up of patients receiving such treatment. Initially, all patients experience flulike symptoms, which are controllable with acetaminophen or aspirin. Such symptoms usually resolve spontaneously after several months of therapy. More serious side effects, including excessive suppression of blood counts, irritability, high fevers, severe asthenia, reversible lower extremity bilateral neuritis, retinopathy, hypothyroidism, depression, sarcoidosis and left-sided heart failure, may require cessation of INF-α therapy. Exacerbation of the depression is a serious side effect of INF and should be considered as a rationale for denying patients this treatment option unless unusual circumstances exist. The role of pegylated INF therapy versus hydroxyurea therapy will be defined only after the performance of a randomized phase III trial in newly diagnosed high-risk ET and PV patients.

The use of small molecule inhibitors of JAK2 for the treatment of advanced forms of MF has recently received approval by regulatory agencies in the United States and likely will in the near future in Europe. The use of ruxolitinib or other JAK2 inhibitors in PV patients has been exclusively explored in patients who are resistant or intolerant to hydroxyurea. These agents appear capable of reducing hematocrit levels, reducing the need for phlebotomy, and reducing the degree of splenomegaly, but have not been associated with dramatic changes in histopathologic abnormalities, platelet numbers, WBC numbers, JAK2V617 allele burden, or elimination of cytogenetic abnormalities. These drugs both in PV and PMF have a remarkable effect on reducing the severity of intractable pruritus that not infrequently affects PV patients. Indiscriminate use of such JAK2 inhibitors in PV patients is discouraged. Patients considering such options should be entered on clinical trials that are constructed to assess their role in the treatment of PV. Symptomatic management of the PV patient may be complicated by the occurrence of intractable pruritus. Normally, the pruritus occurs on exposure to sudden body cooling, especially after a warm bath, and is experienced by as many as 40% to 60% of patients treated with phlebotomy. Aquagenic pruritus is not unique to PV, and in one series of patients presenting to a dermatology clinic, 31% had PV, but in the remainder, an underlying hematologic malignancy could not be detected. Aquagenic pruritus in MPN patients and in patients without an associated malignancy was associated with lactose intolerance. In some instances, multiple family members are affected, suggesting that genetic factors might predispose individuals to this symptom. In some studies, basophils and mast cells have been shown to be involved by JAK2V617F in patients with aquagenic pruritus and PV, likely leading to the elaboration of mediators that lead to itching. The frequency of pruritus appears to be somewhat lower in patients treated with myelosuppressive agents. This observation is related to the probable relation between pruritus and degranulation of tissue mast cells and circulating basophils. Some uncontrolled studies have attributed pruritus to hyperhistaminemia or severe iron deficiency, with relief

associated with the use of histamine antagonists or ferrous sulfate. Iron replacement is frequently not possible because it can lead to dangerous elevations of the RBC mass. In a number of instances, however, iron replacement has been possible with disease control with INF-α. The association between pruritus and tissue infiltration by mast cells would appear to explain the response of occasional patients to photochemotherapy with psoralens and ultraviolet irradiation. At present, INF therapy for pruritus appears to be extremely useful. In addition, 80% of patients with pruritus have been reported to respond to paroxetine or fluoxetine, selective serotonin uptake inhibitors. Other effective options include anticonvulsant drugs such as pregabalin. As mentioned, the JAK2 inhibitors are extremely effective in relieving the pruritus associated with PV, but in occasional patients, this effect, unfortunately, is not sustained.

Budd-Chiari syndrome is a catastrophic illness that can lead to significant morbidity and mortality in a patient with PV. Patients with MPN are at a high risk of developing this syndrome. Independently, the use of oral contraceptive pills and congenital and acquired thrombophilic factors are involved in its development. A number of cases of hepatic vein thrombosis have been reported in nonpolycythemic women taking oral contraceptives. Although no data are available, one must be concerned about the use of oral contraceptives in women with PV.

The optimal approach to the problem of Budd-Chiari syndrome is obviously preventive and involves maintenance of normal blood values in the patient with PV. When the Budd-Chiari syndrome develops, the prognosis without treatment is dismal. The goals of therapy are to prevent further propagation of thrombus, relieve the intense hepatic congestion, and manage the severe ascites that often plague these patients. If untreated, these patients often have a slowly progressive course, with deterioration and death occurring within 3.5 years. Spontaneous resolution of the hepatic vein occlusion rarely occurs. Diuretics may be of value in the treatment of the ascites but do not affect the long-term outcome. Thrombolytic therapy within 24 hours of onset of diagnosis with urokinase (240,000 units/hr for 2 hours followed by 60,000 units/hr) or tissue plasminogen activator (0.5-1.0 mg/hr) directly infused into the thrombosed hepatic vein for 24 hours results occasionally in success. Even if therapy is delayed for 2 to 3 weeks, a favorable outcome can be achieved in some instances with thrombolytic therapy. Such therapy is not innocuous because bleeding can complicate the course of therapy. Angioplasty of localized segments of the hepatic vein can result in the relief of symptoms in the majority of patients, but the risk of restenosis is high. Anticoagulant therapy with Coumadin may have a role in the prevention of further clot formation, but there has been no definitive evidence that such therapy promotes resolution of established thromboses. Several newer anticoagulants that act by direct thrombin or factor Xa inhibition have no natural antidote and are being increasingly used for various prophylactic and therapeutic indications. As such, these new anticoagulants will inevitably pose major challenges in the treatment of MPN patients who are at high risk of bleeding. Indiscriminate use of such anticoagulants before considering the downsides of their lack of reversibility in a group of patients at such a high risk of hemorrhage is likely not prudent and will require further careful study.

The clinical deterioration of patients with Budd-Chiari syndrome results from damage to the hepatocytes from necrosis associated with marked elevation in sinusoidal pressure coupled with ischemia from reduced hepatic arteriole perfusion. The only rational therapeutic intervention, therefore, involves some sort of portal vein decompression to achieve an effective reduction of sinusoidal pressure. A variety of surgical procedures resulting in portal-splenic decompression have been shown to be of value in patients with Budd-Chiari syndrome. Transjugular intrahepatic portosystemic shunt (TIPS) placement has been used as a bridge to liver transplantation. Recent technical advances in the procedure and the introduction of specially coated stents have greatly improved the frequency of shunt patency, sometimes avoiding the need for liver transplantation. The indications for TIPS include recurrent variceal bleeding and refractory ascites. Surgical portosystemic shunts may reverse hepatic necrosis and prevent cirrhosis. The 5-year survival rate after surgical shunts ranges from 75% to 94%. Liver transplantation is a potential option for treatment of those patients with continued hepatic decompensation. The indications for liver transplantation are cirrhosis, fulminant hepatic failure, and failure of a portosystemic shunt. The overall actuarial survival at 1 year was 76% and was 68% at 10 years. Because PV is a slowly progressive disease, transplantation should not be withheld from these patients. Pretransplant predictors of mortality based on a multivariable analysis were impaired renal function and a history of a shunt. The hematologic consequences of polycythemia must be aggressively treated in the posttransplantation setting; the hepatic vein occlusion may reoccur in the transplanted liver.

Therapy of cerebral vein thrombosis and sinuses includes anticoagulation with heparin to arrest the thrombotic process and to prevent pulmonary embolism. Low-molecular-weight heparin (LMWH) should be started as soon as the diagnosis is confirmed even in the presence of hemorrhagic infarcts. After the acute phase, oral anticoagulants are given for 6 months after a first episode or longer if the MPN is not well controlled. There is currently no available evidence from randomized clinical trials regarding the efficacy or safety of thrombolytic therapy.

The performance of any surgical procedures on patients with PV is, as previously discussed, accompanied by excessively high morbidity and mortality. Elective surgery should not be contemplated unless the patient's hematologic values have been normalized for several months. The longer the hematologic control has been in effect, the lower the incidence of postoperative complications. If emergency surgery is required, the patient should be phlebotomized rapidly until a normal hematocrit is reached, and platelets should be available in case excessive perioperative or postoperative bleeding occurs. After emergency or elective surgery, the patient should be mobilized as soon as possible, and strong consideration should be given to anticoagulation with LMWH unless the patient has some contraindication. Dental extractions can also result in excessive hemorrhage and should not be performed unless the patient is under strict hematologic control.

Perhaps the most difficult and frustrating period encountered during the clinical course of a patient with PV is the development of post-PV MF. The origins, manifestations, and management options are discussed in detail in Chapter 69.

Limited information is available concerning the treatment of patients who develop acute leukemia after PV. The overwhelming majority of such cases involve myeloid leukemias. The leukemia is frequently preceded by post-PV MF but not always. Patients with post-PV MF and acute leukemia frequently have greater than 20% blasts in the peripheral blood but far fewer blast cells in the BM, which has led to a hypothesis that the leukemia is originating from an extramedullary site, particularly the spleen. These cases tend to have a more indolent course, but patients with a greater degree of BM infiltration have a more highly proliferative form of leukemia that is associated with an even more aggressive course. The optimal treatment of such patients is unknown. In elderly adults with significant comorbidities, the choice not to institute chemotherapy is a reasonable option. These patients are frequently elderly, and poor results with standard regimens have been reported. Patients rarely achieve a complete remission but rather return to a clinical condition that resembles their original MPN for limited periods of time. In a retrospective analysis on 23 patients with leukemic transformation of PV, the median patient age was 68 years, and leukemia developed a median of 12.8 years from the diagnosis of PV. Twelve of the 14 patients in whom cytogenetic analyses were performed had complex cytogenetic abnormalities associated with high-risk leukemias. Fifteen patients were treated with palliative measures and had a median survival of 2.5 months. Of the eight patients treated with standard induction therapy, one obtained a complete remission, and seven died without obtaining a response. The median survival time of these chemotherapy-treated patients was 5.6 months. The median survival time of the entire cohort of 23 patients was 2.9 months. This poor outcome is likely the result of clinical and biologic features of the acute leukemia, advanced patient age, unfavorable cytogenetics, and patient comorbidities associated with advanced

age. Selected patients are likely to tolerate and to have a favorable outcome with allogeneic stem cell transplantation and reduced intensity conditioning. In fact, the only long-term survival with post-PV leukemia has been observed in patients receiving allogeneic stem cell transplantation. Whether the patients should receive some form of induction chemotherapy before receiving conditioning therapy for preparation of the transplant or proceed directly to transplant is a decision that varies from patient to patient and from center to center. Most patients with PV-related acute leukemia should be considered candidates for experimental therapeutic strategies. Recently, promising results with the use of DNA hypomethylating agents such as decitabine or azacitidine have been reported with 50% to 60% of patients achieving clinically significant responses persisting for 6 to 24 months in the majority of cases. These chemotherapeutic regimens can frequently be administered as an outpatient but require treatment for at least six monthly cycles before clinical responses can be evaluated. Although many of these patients do not achieve true complete remissions (CRs), their prolonged survival and quality of life, at least based upon single-institutional studies, appears to be superior to that achieved with standard induction chemotherapy. Rare clinical responses have also been reported with the use of the oral JAK2 inhibitor bruxolitinib. The use of hypomethylating agents, JAK2 inhibitors, or both is now being explored as bridging therapies before patients receive allogeneic transplants.

Polycythemia vera occurs frequently during the childbearing years. A discussion of contraception options is imperative because the use of oral contraceptive pills may be associated with an increased risk of deep venous thrombosis as well as splanchnic vein thrombosis. It seems prudent to entertain alternative forms of contraception with such individuals. Discontinuation of hydroxyurea in both men and women desiring to have a child are recommended. Hydroxyurea is capable of inducing azoospermia in men, frequently limiting their ability to father a child. Pregnancy is itself a prothrombotic condition. PV in a pregnant individual has been reported to lead to an increased incidence of fetal wastage, with 30% of pregnancies in PV patients terminating in spontaneous abortions. In addition, preeclampsia occurs more frequently in these women. A team approach requiring close communication between an obstetrician skilled in providing care for high-risk pregnancies and the responsible hematologist provides the optimal integration of care to the mother and the child. Pregnancy in PV patients is frequently associated with a gradual normalization of blood values, and it is not unusual for a woman who has required extensive therapy for control of her disease to no longer require phlebotomies during pregnancy. Delivery appears not to be complicated by excessive hemorrhage, but the postpartum period carries an increased risk of venous thrombosis. Although some degree of hematocrit level normalization can be explained by expansion of the plasma volume or by nutritional deficiencies that occur during pregnancy, it is unlikely that these factors can be solely responsible. It seems more reasonable to assume that the high estrogen levels characteristic of pregnancy suppress erythropoiesis. After completion of the pregnancies, the patients' hematologic values slowly drift back to their previously elevated values in parallel with the return to normal estrogen levels. Because pregnancy is usually associated with spontaneous control of the polycythemic state, no specific therapy is required except for careful observation. If needed, therapy should be limited to phlebotomy and low-dose aspirin therapy because of the mutagenic effects of chemotherapeutic agents. Aggressive treatment of hypertension is imperative, as well as attention to the risk of developing preeclampsia and toxemia, which should be treated in a standard fashion. In individuals with a history of repeated spontaneous abortions associated with placental infarction, consideration should be given to low-dose aspirin with LMWH therapy, making sure that these agents are discontinued at the time of delivery to avoid the risk of excessive hemorrhage. If this approach is not successful, INF therapy is suggested because it is not known to be leukemogenic or teratogenic and does not cross the placenta. In the puerperium, thromboprophylaxis with 6 weeks of LMWH therapy is recommended. Aggressive intervention with hematocrit levels maintained below 45% and aspirin therapy with LMWH is associated with a positive outcome for the pregnancy. Breastfeeding is recommended if the mother is receiving therapy with heparin or Coumadin as long as the baby receives adequate supplementation with vitamin K. Rapid mobilization of the mother after delivery is of great importance.

Because PV is ultimately a stem cell disorder, it should be possible to achieve a cure with stem cell transplantation. Thus far, the majority of patients undergoing allogeneic stem cell transplantation have been relatively young (<50 years of age) and have been transplanted after evolution to MF, MDS, or acute leukemia. Transplantation during the polycythemia phase of the disease is rarely appropriate.

FUTURE DIRECTIONS

The discovery of JAK2V617F mutations has led to a more comprehensive understanding of the pathophysiology of the MPNs, including PV. There is no question that the diagnostic tests for JAK2V617F and exon 12 mutations of JAK2, as well as mutations in HIF-1, HIF-2, the EPO receptor, and PHD have revolutionized the diagnostic approach to patients with erythrocytosis. Continued efforts are clearly needed to identify the so-called pre-JAK2V617 mutation and to assess its effects on stem cells. PV is a stem cell disease that will ultimately require curative therapies at a minimum to reduce the numbers or at best to eliminate malignant stem cells if curative small molecule therapies are to become a reality. Before the JAK2V617F allele burden is used as a biomarker for outcomes of novel therapeutic approaches to treat patients with PV, studies are needed to determine the extent of reduction of allele burden that would be predictive of altering the natural history of PV and eliminating complications from thrombotic episodes or evolution to MF or acute leukemia. The use of drugs affecting only JAK2 are unlikely to be curative because multiple genetic and epigenetic events likely contribute to the origins and progression of PV. Randomized clinical trials of combinations of drugs, rather than single drugs, and comparing these outcomes with the standard of care are more likely to lead to significant advances in improving the natural history of PV patients.

CHAPTER 68

ESSENTIAL THROMBOCYTHEMIA

Ronald Hoffman, Marina Kremyanskaya, Vesna Najfeld, and John Mascarenhas

Essential thrombocythemia (ET) is a chronic myeloproliferative neoplasm (MPN) characterized by platelet counts in excess of 450 × 109/L, profound bone marrow (BM) megakaryocyte hyperplasia, leukocytosis, splenomegaly, a clinical course punctuated by hemorrhagic or thrombotic episodes, and possible evolution to myelofibrosis (MF) and acute leukemia. ET is a clinically heterogeneous disorder with more than half of patients meeting the criteria for diagnosis being asymptomatic at presentation. ET was first described in 1934 by Epstein and Goedel, who described a patient with an elevated platelet count who had repeated hemorrhagic episodes.

Originally, many clinical investigators questioned whether ET represented a distinct clinical entity. However, extensive descriptions of larger numbers of patients have provided information to dispute this initial skepticism. In 1951, Dameshek speculated that ET might represent one of the myeloproliferative disorders that are now recognized to be hematologic malignancies. Recent investigations have confirmed this concept and clearly demonstrated that the disorder is typically a clonal hematologic malignancy. Many patients, however, meet the criteria for the diagnosis of ET but have polyclonal hematopoiesis.

In 2005, a breakthrough in our understanding of the pathogenesis and management of ET was made with the discovery of the *JAK2V617F* mutation in the majority of patients with chronic MPN. This finding has had a major impact on the classification of and diagnostic approaches to the MPNs as well as creating drug development strategies based on our increasing understanding of their molecular pathogenesis.

EPIDEMIOLOGY

The true incidence of ET is unknown because extensive epidemiologic studies are not available. Although many investigators have indicated that this disorder is very rare, information from several institutions suggests that it occurs considerably more frequently than originally believed. After the incorporation of a platelet channel in automated complete blood cell counts, extreme thrombocytosis has been shown to be a relatively common occurrence in a general hospital setting. The incidence of ET has been reported to be approximately 1.5 to 2.4 patients per 100,000 population annually. Interestingly, a significant increase in the annual incidence rate of ET from 0.69 to 4.35 patients per 100,000 inhabitants through the years 1983 to 1999 was observed in the city of Goteborg, Sweden. This trend was not observed for polycythemia vera (PV) and was most likely attributable to the standard use of automated blood cell counters over the past few decades and likely will in the future be further accentuated by the recent use of a lower threshold platelet count for diagnosis, the availability of *JAK2V617F* testing, and the implementation of World Health Organization's diagnostic criteria. ET and PV have been reported to have an approximately 1 : 1 relative incidence, although a recent epidemiologic study in Sweden indicated that PV was more than twice as common as ET. The Swedish study also indicated that first-degree relatives of patients with an MPN, including ET, had a five- to sevenfold increased risk of developing an MPN, supporting the concept that there are common, strong, shared susceptibility genes that predispose individuals to develop one of the MPNs.[1] The Janus kinase 2 *(JAK2)* mutation has been shown not to be acquired randomly but instead to arise preferentially on a specific *JAK2* haplotype (46/1). The *JAK2* 46/1 haplotype has been shown not only to predispose to *JAK2V617F* positive ET but also to cases of ET with mutations of the thrombopoietin receptor and, surprisingly, to ET not associated with such acquired mutations, again indicating genetic factors playing a role in the susceptibility to developing ET. Recently, the risk of developing ET was shown to be higher in carriers of constitutional *CHEK2* gene mutations.[2] *CHEK2* is a tumor suppressor gene that protects cells from excessive proliferation by regulating cell division. Germline *CHEK2* mutations have been also associated with Li-Fraumeni syndrome, some lymphoid and solid tumors malignancies, and myeloid malignancies. The manner by which germline *CHEK2* mutations might contribute to the development of ET remains the subject of speculation, but it is most closely associated with onset at a young age.

Based on population studies, the disorder appears to occur in individuals with a median age of 67 to 73 years, but in single-institution studies, the median age at diagnosis has been reported to be lower (50-57 years). In most series, there appears to be no gender predilection; although in several reports, a higher prevalence in women has been noted. This discrepancy might be due to an equal frequency in older patients of both sexes but to a second peak frequency at around 30 years of age for women.

Cases of ET have been reported in patients in the pediatric age group, but this is an unusual occurrence. A review of the literature cannot accurately determine the risk of thrombosis or bleeding of ET in childhood, but the clinical course is not entirely benign. The incidence of ET in childhood has been reported to be approximately 1 per 10^7 population, which is 60 times lower than that in adults. Approximately 30% of children with this disorder experience thrombotic or hemorrhagic complications at diagnosis or later in their course, and 50% have splenomegaly. Interestingly, in a recent study, only 20% of pediatric patients with ET, compared with 45% of adult ET patients, had clonal hematopoiesis, and 20% were *JAK2V617F* positive compared with 60% of adult patients.

Several families with multiple members having ET have been described. The prevalence of the *JAK2V617F* mutation in familial cases of MPN has been analyzed in 72 families, including 174 patients (68 with ET). The *JAK2* mutation was found in half of patients with ET, a similar proportion as observed in sporadic, nonfamilial cases. Among 46 families with at least two cases of PV, ET, or primary MF (PMF), the *JAK2* mutation was absent in six families, heterogeneously distributed in 18, and present in all patients with MPN in 22. Thus the *JAK2* mutation does not seem to be required for the development of ET or other MPNs, and this familial clustering cannot be accounted for by the prevalence of *JAK2* 46/1 haplotype.

PATHOBIOLOGY

Greater insights into the mechanisms leading to thrombocytosis in ET have been gained. Patients with ET have normal or near-normal platelet survival. The thrombocytosis is due to increased platelet production by megakaryocytes. Effective platelet production

is increased as much as 10-fold and is associated with an increase in megakaryocyte clustering, volume, nuclear lobe number, and nuclear ploidy.

ET is typically a clonal hematopoietic disorder originating at the level of the pluripotent hematopoietic stem cell. Subsequent analyses have revealed, however, that a significant proportion of nonclonally derived leukocytes exist in addition to the clonally derived population of leukocytes in patients with ET. In one study of 42 patients with ET, 31 patients exhibited clonality of at least one hematopoietic lineage, but the remaining 11 patients had polyclonal origin of all lineages studied. The biogenesis of polyclonal ET remains ill defined.[3] It is possible that small numbers of normal hematopoietic stem cells persist to account for this admixture of nonclonal populations. It has been reported by several groups that ET patients with polyclonal hematopoiesis have fewer thrombotic complications. Interestingly, in some patients, monoclonality of hematopoiesis is restricted to platelets despite the polyclonal origin of the other lineages. Other studies, however, have indicated a common origin of granulocytes, platelets, and B lymphocytes in this disorder. Such studies raise the possibility that the malignant transformation leading to ET occurs at a number of cellular stages along the hematopoietic cellular hierarchy.

The biologic behavior of megakaryocyte progenitor cells present either in the BM or in the peripheral blood of patients with ET has been extensively studied. In each of these studies, the use of serum-containing culture systems has led to the detection of increased numbers of assayable progenitors. These data support the concept that the principal abnormality is an expansion of the progenitor cell pool. In addition, colonies were noted to appear in the absence of exogenous cytokines. A second subpopulation of colony-forming unit–megakaryocyte (CFU-MK) assayed from patients with ET was also shown to remain responsive to the addition of cytokines, suggesting the presence of both an MPN clone not requiring exogenous cytokines.

Several laboratories have demonstrated that megakaryocyte progenitor cells isolated from ET patients are characterized by increased sensitivity to the action of several cytokines, including interleukin-3 (IL-3), IL-6, and thrombopoietin. Investigators have explored the possibility that the defect in ET might actually be due to resistance to inhibitors of megakaryocytopoiesis; ET CFU-MK are significantly less sensitive to the inhibitory effects of transforming growth factor-β (TGFβ) and have a limited response to the inhibitory effects of high concentrations of autologous platelet lysates. TGFβ was shown to be primarily responsible for the inhibitory activity present in such platelet lysates. Some combination of increased sensitivity to growth factors that promotes platelet production and disrupted sensitivity to negative regulators of thrombopoiesis at the level of the megakaryocyte progenitor cell or megakaryoblast likely accounts for the thrombocytosis in patients with ET.

Erythroid progenitor cells in ET can also proliferate in response to the small amounts of cytokines. Erythroid colony formation in the absence of exogenous erythropoietin is a hallmark of the proliferative defect that characterizes PV. Burst-forming unit–erythroid can be assayed from both BM and peripheral blood of patients with ET and form erythroid colonies in the absence of exogenous erythropoietin. Such an abnormality in these nonpolycythemic patients probably indicates an underlying intracellular defect shared by progenitor cells in many MPNs. Thrombopoietin is the primary physiologic regulator of thrombopoiesis. This growth factor acts by binding to its cell surface receptor, MPL. The thrombopoietin receptor is expressed by $CD34^+$ hematopoietic progenitor cells, megakaryocytes, and platelets. Normal or slightly elevated thrombopoietin levels have been observed in patients with ET. This is in contrast to erythropoietin levels in PV and ET, which are uniformly decreased. Furthermore, expression of the thrombopoietin receptor and its mRNA have been shown to be dramatically reduced in the platelets of patients with ET. A possible explanation for the diminished expression of platelet MPL and the associated thrombocytosis has been provided by the study of several animal models, which has confirmed that decreased expression of MPL in late-stage megakaryocytes and platelets concurrent with persistent expression of MPL on early megakaryocytes and progenitor cells results in thrombocytosis. Thrombopoietin serum levels are controlled by platelet mass through MPL-mediated thrombopoietin uptake and degradation. The reduced platelet MPL expression occurs not only in ET but also in PV and PMF and has been shown to be a downstream event of *JAK2V617F* and likely results in the decreased capacity of platelets to absorb thrombopoietin, resulting ultimately in an increased megakaryocyte mass and thrombocytosis.

Whereas the *JAK2V617F* mutation is present in 40% to 60% of patients with ET, gain-of-function mutations involving the thrombopoietin receptor, *MPLW515L* and *MPL515K*, are present in approximately 1% to 3% of patients with ET.[4] About 60% of patients with *MPL* mutations have the *W515L* mutation and 40% the *W515K* mutation. The mutant allele burden is greater than 50% in 50% of *W515K* patients as compared with 17% of *W515L* patients. More than 50% of patients with MPL mutant alleles are also *JAK2V617F* positive. In ET, both *JAK2V617F* and MPL mutations arise preferentially on a specific constitutional *JAK2* 46/1 haplotype. Two hypotheses have been proposed to account for this predilection: 46/1 is inherently genetically more unstable (hypermutability hypothesis) or 46/1 confers a growth advantage that favors the predominance of *JAK2V617F* hematopoiesis (fertile ground hypothesis). The association of MPL mutations with the *JAK2* 46/1 haplotype strongly favors the hypermutability hypothesis rather than the fertile ground hypothesis.

JAK2 is a cytoplasmic tyrosine kinase that plays a key role in mediating intracellular signaling from a variety of growth factors, including IL-3, erythropoietin, granulocyte macrophage colony-stimulating factor (GM-CSF), granulocyte colony-stimulating factor (G-CSF), and thrombopoietin. Coexpression of *JAK2V617F* with a homodimeric type 1 cytokine receptor (including erythropoietin, thrombopoietin, or G-CSF) is necessary for hormone activation of JAK-STAT (signal transducer and activator of transcription) signaling pathways and for hematopoietic cell proliferation to become growth factor independent. The *JAK2V617F* mutation is present in ET patients with both clonal and polyclonal hematopoiesis. Patients with clonal hematopoiesis have a higher *JAK2V617F* allele burden (26%) than patients with polyclonal hematopoiesis (16%). The relative size of the *JAK2V617F* clone is often small and remains stable over time in patients with both clonal and polyclonal hematopoiesis. Although an allele burden higher than 50% indicating the presence of granulocytes homozygous for *JAK2V617F* has been found in 70% of PV patients, it has been observed less frequently in ET patients. All PV patients have assayable erythroid colonies that are homozygous for *JAK2V617F*, even in PV patients with a low burden of *JAK2V617F*. By contrast hematopoietic colonies cloned from ET patients are occasionally *JAK2V617F* homozygous. The transition from *JAK2* heterozygous to homozygous progenitors is a consequence of homologous recombination. These studies suggest that such an event is characteristic of PV but rarely occurs in ET. If such an event occurred in ET, it would likely lead to a transition from an ET phenotype to a PV phenotype. Some investigators, but not all, have reported a higher allelic burden of *JAK2V617F* in platelets compared with granulocytes in patients with ET, and that the allelic burden in PV and PMF is higher in granulocytes than platelets. *JAK2V617F* is observed only in platelets in rare patients with ET. *JAK2V617F* can be detected not only in granulocytes and platelets of ET patients but also erythroblasts. Recently, Lambert and coworkers,[3] using single-nucleotide polymorphism (SNP) genotyping of the *JAK2V617F* mutant alleles reported that there were at least two *JAK2V617F* mutational events occurring in 10 of 11 cases, suggesting that multiple independent abnormal clones were involved in the origination of ET. Others have, however, reported that the true prevalence of biallelic *JAK2* mutations is approximately 5% to 10%. These findings are in contrast to the results obtained in PV patients in whom only a single SNP is associated with the mutated *JAK2*. These data have led some investigators to question if such biallelic *JAK2V617F* forms of ET truly represent a malignant disease but are rather a benign stem cell clonal disease.

One of the ongoing mysteries of the biology of *JAK2V617F* has been the lack of insight of how this mutation can participate molecularly in such phenotypically diverse MPNs. Increased basal signaling in both early and later stages of myeloid differentiation appears to be

common to all MPN. In PV, *JAK2V617F* produces an increased phosphorylation of STAT. In PV, uniformly increased phosphorylated STAT3 and STAT5 in BM cells has been observed, but in ET, normal or increased phosphorylated STAT3 but reduced phosphorylated STAT5 has been noted. STAT3 is a pivotal regulator of megakaryocytopoiesis that might provide an explanation for its exclusive upregulation in ET. To further examine the differences between hematopoiesis in *JAK2V617F* ET and PV, the gene expression changes in *JAK2V617F* heterozygous erythroid colonies have been examined. Erythroblasts from ET patients were characterized by enhanced expression of genes associated with interferon (INF) signaling and phosho-STAT1 compared with PV erythroblasts.[5] STAT1 is essential for INF-γ signaling. Increased STAT1 in normal $CD34^+$ cells has been shown to favor megakaryocytic but reduce erythroid differentiation, creating a differentiation pattern that resembles ET. Furthermore, inhibition of STAT1 signaling in ET hematopoietic progenitor cells led to enhanced erythropoiesis and reduced megakaryocytopoiesis. These studies suggest that in ET, *JAK2V617F* induces simultaneous activation of STAT5 and STAT1 pathways, but in PV, the relative reduced levels of phosphol-STAT1 reduces a brake favoring more profound erythropoiesis. The MPL mutations occurring in ET patients trigger conformational changes in the receptor, bringing in close proximity two molecules of bound *JAK2* for transphosphorylation and activation of the signaling cascade.

The methodology used to detect *JAK2V617F* can influence the proportion of ET patients documented to be positive for the mutation. The frequency of *JAK2V617F*-positive ET ranges from 40% to 60% of cases. This still leaves a subset that does not possess MPL mutations and that is *JAK2V617F* negative. ET patients without mutated *JAK2* are characterized by a lower expression pattern of JAK/STAT target genes and lower levels of STAT3 phosphorylation, indicating that alternative signaling pathways are likely responsible for the ET phenotype in these patients. This hypothesis has been verified by the description of a patient with *JAK2V617F*-negative ET who also lacked an MPL mutation but was characterized by an acquired t(5;9) chromosomal translocation that resulted in the fusion of *KANK1* and platelet-derived growth factor receptor β (PDGFRβ).[6] In this patient, the *KANK1* gene is disrupted. *KANK1* is a putative tumor suppressor gene present at 9p24, a region that is deleted in a variety of cancers. *KANK1* expression has been shown to be diminished in patients with *JAK2V617F* PV and ET. *KANK1* inhibits cell migration and actin polymerization through the modulation of Rho GTPases, which play a role in the terminal phases of platelet generation. *KANK1*–PDGFRβ activates STAT5 transcription factors but does not require JAKs, indicating that other signaling pathways result in the thrombocytosis observed in such patients.

The clinical phenotype of patients with *JAK2V617F*-positive and -negative ET appears to differ. At diagnosis, patients with the mutation tend to be older and to have a higher hemoglobin level and a higher neutrophil count but a lower platelet count than patients with *JAK2V617F*-negative ET. Patients with *JAK2V617F*-positive ET have a BM that is more hypercellular and is characterized by greater degrees of erythroid and granulocytic hyperplasia. Serum erythropoietin levels are lower in *JAK2V617F*-positive patients, and they have lower serum ferritin levels. In addition, the rate of thrombosis has been suggested by some, but not all, investigators to be higher in *JAK2V617F*-positive ET patients. Furthermore, a greater number of ET patients who have the mutation eventually go on to develop PV. *JAK2V617F*-positive patients have been reported to require smaller doses of hydroxyurea to lower their platelet counts. Campbell et al have hypothesized that because *JAK2V617F*-positive ET shares many phenotypic similarities with PV, these two disorders should be considered as a continuum rather than being categorized as two separate diseases. The presence of the *MPLW515K* mutations in ET patients has been reported to be associated with lower hemoglobin levels and higher platelet counts as well as preferential expansion of the numbers of megakaryocytes at the expense of erythroid precursors as observed in BM biopsy specimens.

Discordance between the percentage of clonal granulocytes and the percent of *JAK2V617F*-positive granulocytes has led some investigators to speculate that the development of a clonal form of ET may precede the acquisition of the *JAK2V617F* mutation or that other mutations might be playing a role in the origins of ET. In mouse models, the inhibitory adaptor protein Lnk has been shown to be associated with downmodulation of erythropoietin and thrombopoietin signaling. Lnk can bind to wild-type *JAK2*, *JAK2V617F*, wild-type MPL, and *MPLW515L*. Lnk levels are upregulated and correlate with an increase in the *JAK2V617F* allele burden in MPN patients. In *JAK2V617F*-positive ET, Lnk mRNA expression is upregulated and serves to modulate *JAK2V617F*-mediated cell regulation. Thrombopoietin-mediated signaling regulates Lnk expression at both the mRNA and protein levels. Furthermore, acquired Lnk mutations have been observed in 1% to 5% of ET patients without *JAK2V617F*. The inactivating Lnk mutations in ET patients result in JAK/STAT activation, leading to high levels of STAT3 and STAT5 activation, leading to either ET or PMF.[7]

An additional gene that is mutated in ET is *TET2* (the ten–eleven translocation gene, which encodes for a hydroxylase that is able to hydroxylate methylated cytosine). These mutations result in loss of function, leading to increased DNA methylation and a reduction in hydroxymethyl cytosine. *TET2* mutations occur in 11% of ET patients but are not specific to ET because they can also occur in a variety of other myeloid malignancies. Mutations in *TET2* can occur either before or after mutations of *JA2V617F* or *MPL*. Mutations in the gene for isocitrate dehydrogenase (IDH) occur in 0.9% of ET patients and can functionally lead to similar effects as *TET2* mutations on DNA methylation. Furthermore, disrupting mutations of ASXL, which occur in 36% of PMF patients, are infrequent in ET as are mutations of *CBL* or *EZH2*.

Furthermore, the transcription factor NF-E2 has been shown to be overexpressed in the cells of patients with MPNs independent of the presence or absence of *JAK2V617F*. NF-E2 acts as an epigenetic transcriptional regulator and chromatin modifier. Genetically engineered mice that overexpress NF-E2 have been created and are characterized by extreme thrombocytosis and leukocytosis, normal hemoglobin levels, and BM hypercellularity, a clinical picture similar to that observed in ET patients.[8] These animals die of gastrointestinal hemorrhagic events, and 15% evolve to a form of acute myeloid leukemia (AML). The upregulation of NF-E2 can be corrected by treatment with inhibitors of histone deacetylases, suggesting that downregulation of NF-E2 using similar agents in ET patients should be explored, especially because the use of histone deacetylase inhibitors is frequently associated with dose-limiting thrombocytopenia.

The cause of the increased risk of developing hemorrhagic and thrombotic events associated with ET remains the subject of investigation. Thrombotic complications occur most frequently in patients older than age 60 years; patients with a history of a thrombotic event; and individuals with cardiovascular risk factors, including tobacco use, hypertension, or diabetes mellitus, but hemorrhagic events occur almost exclusively in individuals with extremely high platelet counts ($>1000 \times 10^9$/L).[9] In addition, leukocytosis (>11,0000/L) and *JAK2V617F* positivity have been associated with the development of arterial thromboses. Platelet counts in excess of 1000×10^9 are associated with a lower risk of developing arterial thromboses. The incidence of thrombotic events in ET patients ranges from 1.5 to 6.6 percent per patient-year. The thrombotic events in ET are largely arterial, but venous thromboses also occur not infrequently.[10] *JAK2V617F*-positive patients compared with patients without the mutation have a higher risk of developing thrombotic events, but a dose-dependent correlation between allele burden and the development of clinical symptoms has not been demonstrated. A subset of young patients who are asymptomatic and remarkably free of such complications has also been described. Unfortunately, catastrophic thrombotic complications can be seen in both young and elderly patients. The age-related differences in the frequency of these events have been attributed to the coexistence of vascular disease in older patients.

Some progress has been made in defining the relationship between platelet numbers and the risks for thrombotic and hemorrhagic events in ET. In a randomized trial of patients at a high risk of developing

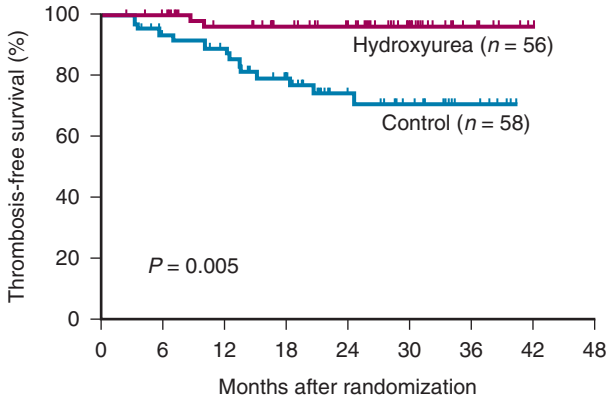

Figure 68-1 PROBABILITY OF THROMBOSIS-FREE SURVIVAL IN 114 PATIENTS WITH ESSENTIAL THROMBOCYTHEMIA TREATED WITH HYDROXYUREA OR LEFT UNTREATED. *(From Cortelazzo S, Finazzi G, Ruggeri M, et al: Hydroxyurea for patients with essential thrombocythemia and a high risk of thrombosis.* N Engl J Med *332:1132, 1995.)*

a thrombotic event (older than 60 years of age, a history of a thrombotic episode, or both), the reduction of platelet numbers was highly effective in preventing additional thrombotic events (Fig. 68-1). Furthermore, the incidence of thrombotic events has been shown to be closely correlated with the duration of thrombocytosis.

Several groups have now confirmed that the degree and duration of bleeding in ET patients is correlated with platelet numbers. Bleeding events appear to occur exclusively when the platelet counts are excessively high and are reduced in number when the platelet count returns to normal. The clinical spectrum of bleeding in ET patients closely resembles that observed in von Willebrand disease. Several groups have now shown that high platelet counts ($>1000 \times 10^9$/L) are associated with an acquired form of von Willebrand syndrome and that reduction of platelet numbers is associated with correction of the von Willebrand syndrome–like abnormalities and cessation of bleeding episodes.[11] The mean platelet count in patients with ET and acquired von Willebrand disease is $2050 \pm 1107 \times 10^9$/L. An increase in the number of circulating platelets appears to favor the adsorption of larger von Willebrand multimers onto platelet membranes, resulting in their removal from the circulation and their subsequent degradation.

Platelets in patients with ET have been known for a considerable time to be qualitatively abnormal. Although both increased and decreased platelet reactivity has been described, these findings have not been definitively associated with thrombohemorrhagic complications with two noteworthy exceptions—erythromelalgia, in which the prompt relief of symptoms by cyclooxygenase inhibitors provides direct evidence that prostaglandins play a role in the development of vascular occlusion, and acquired von Willebrand syndrome, which is a major cause of bleeding in patients with ET. Recently, both ET and PV platelets have been shown to contain a large proportion of immature platelets that have been recently released from the BM. Such immature platelets have increased hemostatic activity as demonstrated by a heightened response to thrombin and greater expression of P-selectin. Hydroxyurea has been shown to be capable of reducing the number of immature platelets in ET, which might partly be responsible for the reduced thrombotic risk associated with its use.

Abnormal platelet aggregation has been reported in 35% to 100% of patients with ET. The majority of such studies have used conventional platelet aggregation studies performed on platelet-rich plasma. The simultaneous measurement of platelet aggregation and adenosine triphosphate–dense granule release by whole-blood platelet lumiaggregometry has been used to study platelet function in ET patients with the hope of identifying patients at a risk of developing thrombosis. A prospective analysis of large cohorts of patients has not been performed to confirm the utility of such assays.

Abnormal aggregation studies have not been successful in predicting the incidence of episodes of hemorrhage or thrombosis. In ET, platelet aggregation is classically defective in response to epinephrine, adenosine diphosphate (ADP), and collagen but is usually normal with arachidonic acid and ristocetin. Characteristically, in ET, the first wave of aggregation is diminished, and the second wave of aggregation is absent in response to epinephrine. Interestingly, preincubation of ET platelets with thrombopoietin partly corrects the impaired aggregation in response to epinephrine, ADP, and collagen. An acquired form of platelet storage pool disease occurs frequently in ET. Platelet α-granule content and the release of the content of granules are abnormal, resulting in elevated plasma levels of platelet factor-4 and β-thromboglobulin.

Because the content of α-granule constituents has been reported to be normal in ET megakaryocytes, the synthesis of these molecules is not believed to be abnormal; rather, the release of α-granule constituents is believed to be a consequence of platelet activation. The finding of an acquired storage pool defect again does not correlate with platelet numbers or with the occurrence of clinical symptoms. Numerous individual functional platelet abnormalities have been demonstrated. A defect in the metabolism of arachidonic acid by lipoxygenase has been documented, as have decreased numbers of platelet receptors for prostaglandin D_2 and adrenergic receptors for epinephrine. Platelets from patients with thrombotic episodes have been found to be capable of increased generation of thromboxanes and to have an increased affinity for fibrinogen. Elevations in β-thromboglobulin and serum thromboxane levels in ET patients are validated indices of enhanced in vivo platelet activation and possibly thrombin generation. Such abnormalities are not present in patients with secondary thrombocytosis and may provide some explanation for the high incidence of thrombosis associated with ET. The antithrombotic activity of aspirin has been attributed to its ability to permanently and selectively inactivate platelet cyclooxygenase-1 (COX-1), thereby blocking thromboxane biosynthesis. This action has served as the rationale for the widespread use of aspirin in ET patients for thrombosis prophylaxis in the absence of valid controlled clinical trials. Recently, however, COX-2 has been shown to be overexpressed by the megakaryocytes and platelets of ET patients; COX-2 can also contribute to the enhanced biosynthesis of thromboxanes in ET.[12] Low-dose aspirin can only partially correct this enhanced thromboxane synthesis, likely because of the increased COX-2 activity associated with the increased rate of platelet generation associated with ET, providing the rationale for the use of more aggressive aspirin scheduling or the addition of thromboxane receptor A_2 antagonists to reduce the incidence of thrombotic events.

The platelet activation observed in ET has also been linked to Src, which is a nonreceptor tyrosine kinase particularly abundant in platelets. In thrombin-stimulated platelets, Src kinase is required for platelet aggregation. In normal resting platelets, Src is silent, but its catalytic activity is activated in response to specific stimuli. In ET platelets, Src kinase is dephosphorylated into its potentially active form as a consequence of its interaction with the tyrosine phosphatase, Src-homology 2 (SHP-2). ET platelets are therefore primed for stimulation by low concentrations of thrombin for faster Src signaling, which ultimately leads to platelet cytoskeleton rearrangement and aggregation. In ET, Src dephosphorylation may be triggered in vivo by a variety of stimuli, including a high platelet count, high shear stress, high concentrations of thrombopoietin, and procoagulant activities. This preactivation of Src that is characteristic of ET and the related platelet hyperactivity is likely to account for the hypercoagulable state that is emblematic of ET.

Microvascular thrombosis causing digital or central nervous system ischemia leads to a variety of clinical syndromes closely associated with ET. The survival of platelets in ET patients with erythromelalgia and thrombosis has been shown to be reduced to 4.2 ± 0.2 days compared with normal platelet survival in asymptomatic ET patients (6.6 ± 0.3 days) and patients with reactive thrombocytosis (8.0 ± 0.4 days). Thrombosis in this setting is associated with an increased platelet turnover, which can be quantitated flow cytometrically by measuring the number of platelets most recently released into the circulation (reticulated platelets). Treatment of erythromelalgia with aspirin increased mean platelet survival from 4.0 ± 0.3 days to

6.9 ± 0.4 days and was associated with a significant elevation of platelet numbers. These findings suggest that erythromelalgia results from platelet-mediated thrombosis of the arterial microvasculature of the extremities. Complete correction of this ischemic circulatory defect is associated with the use of platelet cyclooxygenase inhibitors, such as aspirin and indomethacin. Agents that do not inhibit platelet cyclooxygenase, such as coumadin, sodium salicylate, dipyridamole, sulfinpyrazone, and ticlopidine, are not active in the treatment of this disorder. Dazoxiben is capable of inhibiting platelet malondialdehyde and thromboxane B_2 synthesis but does not correct the symptoms of erythromelalgia. These findings suggest that prostaglandin endoperoxides play a role in the generation of platelet-associated thrombosis in ET.

One intriguing explanation for the increased risk of thrombosis in patients with ET has been the observation that the total amount of thrombin generated on the platelet surfaces of patients with ET is markedly greater than that generated on the platelet surfaces of normal control participants or patients with reactive thrombocytosis. The molecular basis of this abnormality has not been defined, but it remains possible that an abnormal membrane structure of ET platelets may account for the enhanced thrombin potential that may lead to a relatively high thrombotic risk. Increased numbers of platelet microparticles, as well as increased platelet–neutrophil and platelet–monocyte complexes have been observed in patients with ET. Platelet microparticles support thrombin generation and leukocyte activation. Increased numbers of platelet microparticles have been associated with the development of vascular thrombosis.

Recently, in vivo leukocyte activation has been shown to occur in ET and to be associated with signs of activation of both the coagulation cascade and endothelial cells. Such platelet and leukocyte activation may play a role in the generation of the prethrombotic state that characterizes ET. Interestingly, the presence of the *JAK2* mutation is associated with a greater degree of platelet and leukocyte activation in these patients. Activated neutrophils are able to bind platelets, which triggers the expression of tissue factor as well as endothelial cell activation and damage. From a clinical point of view, several studies have demonstrated that an increased leukocyte count (>11,000 $\times 10^9$) in patients with ET is an independent risk factor for developing arterial thrombosis, especially myocardial infarction, and is associated with an inferior survival rate.[13] Therefore, an important role for leukocytes in the pathogenesis of thrombosis in ET is becoming more evident. Presumably, the leukocytosis in ET patients leads to thrombosis by damaging the vascular endothelium because of the release of reactive oxygen species, intracellular proteases, or both. In addition, a high percentage of leukocytes from ET patients has been shown to have platelets present in phagocytic vacuoles, presumably leading to enhanced platelet clearance. This leukocyte-mediated clearance of platelets has been shown to be diminished in individuals with prior thrombotic episodes.

Direct involvement of endothelial cells of MPN patients by *JAK2V617F* has been recently reported by several groups, which might lead to endothelial dysfunction in subsets of MPN patients, further enhancing the thrombotic predisposition to the development of splanchnic vein thromboses.

CLINICAL MANIFESTATIONS

The presenting symptoms of patients with ET are quite variable. Many patients (12%–67%) reach medical attention fortuitously as a result of the extreme degree of thrombocytosis detected when obtaining a routine blood cell count. In two series, in fact, 76% to 84% of cases were asymptomatic, and the diagnosis was made incidentally. Most patients present with symptoms related to small- or large-vessel thrombosis or minor bleeding. The thrombotic events at diagnosis and during follow-up occurred at rates of 10% to 29% and 8% to 31%, respectively. In general, arterial events predominate over venous events. Presentation with a major bleeding episode is unusual. After thrombocytosis has been detected, 13% to 37% of patients relate symptoms resulting from hemorrhagic events, and 22% to 84% of patients report thromboembolic complications. The thrombotic events primarily involved the microvasculature, with thrombosis of large vessels also occurring. Neurologic complications are common. Table 68-1 lists representative neurologic complaints, of which headache was the most common, with paresthesias of the extremities a close second. There was an extremely high incidence of transient ischemic attacks involving both the anterior and posterior cerebral circulation. These attacks have a sudden onset, last for a few moments, and are frequently associated with a pulsatile headache. The various symptoms occur sequentially rather than simultaneously and can be preceded or followed by erythromelalgia. Transient neurologic symptoms include unsteadiness, dysarthria, dysphoria, motor hemiparesis, scintillating scotomas, amaurosis fugax, vertigo, dizziness, migraine-like symptoms, syncope, and seizures. The syndrome is caused by platelet-mediated ischemia and thrombosis in end-arterial microvasculature. It is not unusual for these symptoms to eventually progress to definitive cerebral infarcts.

Microvascular circulatory insufficiency involving the toes and fingers is frequent. Such events can lead to digital pain, enhanced by warmth; distal extremity gangrene, and classic erythromelalgia. The term *erythromelalgia* refers to a syndrome of redness and burning pain in the extremities. Erythromelalgia, which is characterized by a burning pain and a dusky congestion of swollen extremities, is usually preceded by paresthesias. Cold provides relief to these symptoms, and heat intensifies the symptoms. Patients prefer to wear shoes or slippers without socks and elevate their feet. These symptoms may progress in intensity and lead to peeling of the skin in affected appendages or affected toes or fingers, which then may become cold and ischemic with a dark purplish tinge. Erythromelalgia symptoms

are asymmetric in the majority of cases. Symptoms related to coronary artery disease or transient ischemic attacks may precede or accompany the onset of erythromelalgia. Occasionally, hemorrhagic episodes may occur in patients experiencing erythromelalgia. Platelet counts in patients with erythromelalgia are frequently below 1000×10^9/L, except in patients with concomitant occurrence of erythromelalgia and hemorrhage. The relief of such pain for several days after a single dose of aspirin is diagnostic of erythromelalgia. The specific microvascular syndrome of erythromelalgia is readily explained by platelet-mediated arteriolar inflammation and occlusive thrombosis leading to acrocyanosis and even gangrene.[14] Skin biopsies from affected sites reveal arteriolar lesions without involvement of venules, capillaries, or nerves. The arteriolar endothelial cells are swollen and the vessel walls thickened by cellular swelling and deposition of intracellular material. Compared with atherosclerotic circulatory obstruction, arterial pulses in patients with erythromelalgia remain normal. Other patients develop platelet-mediated acral inflammation and arterial thrombosis, which can progress to ischemic acrocyanosis or necrosis of fingers, toes, and, rarely, the tip of the nose (Fig. 68-2).[15]

Although thrombosis of the microvasculature is generally more frequent, thrombosis of large veins and arteries in patients with ET still occurs commonly.[16] Patient symptoms frequently occur related to large-vessel thrombosis, mostly in the arteries of the legs, the coronary arteries, and the renal arteries. Involvement of the carotid, mesenteric, and subclavian arteries is frequent, and patients characteristically have venous thromboses involving the splenic vein, hepatic veins, or veins of the legs and pelvis. Unexplained thrombosis of the hepatic veins leads to Budd-Chiari syndrome, and thrombosis of the renal vein can result in the development of the nephrotic syndrome.[17] Splanchnic vein thromboses occur predominantly in young women with ET. Patients with this complication are at a high risk of having a poor survival because of hepatic failure or transformation to MF or acute leukemia. It is worth noting that a fraction of patients with idiopathic splanchnic vein thrombosis may present with normal or near-normal blood counts but have an occult MPN based on genetic or histopathologic abnormalities. In a recent review of more than 800 patients with splanchnic vein thrombosis without a diagnosis of an MPN, a mean of 32.7% of patients were *JAK2V617F* positive. More than 50% of these patients subsequently were diagnosed with an MPN. In addition, 2.6% of patients with a cerebral sinus and vein thrombosis were also shown to be *JAK2V617F* positive. These studies suggest that all cases of splanchnic vein thrombosis and likely cerebral sinus and vein thrombosis should be tested for *JAK2V617F* to identify patients with an occult MPN. This high prevalence of *JAK2V617F* positivity has not been observed in individuals with more common kinds of thrombotic events. Priapism is a rare complication of ET, presumably caused by platelet sludging in the corpus cavernosum. In addition, myocardial ischemia and infarction associated with normal coronary angiograms has been reported in patients with ET as has a high incidence of anginal symptoms. A high incidence of aortic and mitral valvular lesions has been reported in patients with MPN, including ET. These valvular lesions resemble previous descriptions of nonbacterial thrombotic endocarditis and may occasionally be the origin of the peripheral arterial emboli observed in these patients. In addition, acute renal failure has been observed after thrombosis of renal arteries and veins in patients with ET. Pulmonary hypertension secondary to alveolar capillary plugging by platelets and megakaryocytes has also been reported in patients with ET.

Hemorrhagic events occur in 3% to 11% of patients with ET; the primary site of bleeding is the gastrointestinal tract.[11] Other sites of bleeding may be the skin, eyes, urinary tract, gums, tooth sockets (after extraction), joints, or brain. Bleeding most often is not severe but occasionally may require red blood cell (RBC) transfusion support. The postoperative period appears to be an extremely precarious time, with a high incidence of bleeding episodes during the immediate postoperative period. This hemorrhagic tendency is likely caused by postsurgical thrombocytosis and the development of acquired von Willebrand syndrome or the use of antithrombotic prophylaxis therapy. Bleeding is closely correlated with a significant increase in platelet counts in excess of 1500×10^9/L and is associated with pseudohyperkalemia. It is important to emphasize that individual patients can experience both thrombotic and hemorrhagic episodes and that patients are not necessarily consistent "bleeders" or "clotters."

Appreciation of the risk of developing thrombohemorrhagic events in asymptomatic patients with ET who are younger than 40 years of age is imprecise at best. Such patients are thought to be at a low risk of developing thrombotic episodes unless they have experienced a prior thrombotic episode or have associated cardiovascular risk factors. With their anticipated long survival, such patients are, however, at a considerable risk of eventually developing symptomatic MF several decades after the initial diagnosis of their MPN. The most common thrombotic complications include migraine headaches in 20% and erythromelalgia in 5% of the patients. Life-threatening hemorrhagic episodes are rare. The degree of leukocytosis has been suggested by some investigators to be useful in discriminating between young patients with a low or high risk to develop a thrombotic episode.

A meta-analysis has revealed that the JAK2V617 mutation is associated with a twofold higher risk of developing either a venous or arterial thrombosis but does not influence the risk of suffering from a hemorrhagic event. Regardless, it is conceivable that the significantly more advanced age and elevated hematocrit and leukocyte levels in mutation-positive patients might contribute to the apparent association between *JAK2V617F* and thrombosis reported in some studies. Vannucchi et al[4] have reported that rare ET patients with a high *JAK2V617F* allele burden are at a particularly higher risk of developing cardiovascular events.

Patients with ET who are older than 60 years of age who have had a prior thrombotic event have a greater risk of developing additional thrombotic events (Table 68-2). By contrast, the incidence of thrombotic and hemorrhagic complications in asymptomatic patients with ET who are younger than 60 years of age who have platelet counts of less than 1500×10^9/L has been shown to be comparable to a normal control population. Gender, hypertension, diabetes mellitus, hypercholesterolemia, and smoking have been shown to be independent risk factors for developing arterial thrombotic complications in ET (see Table 68-2). Investigators continue to search for other acquired or congenital defects of hemostatic mechanisms, such as the factor V Leiden mutation, prothrombin G20210A gene mutation, and so on, to better understand why many patients remain asymptomatic but others experience a serious thrombosis. Screening of patients for such thrombophilic states may identify patients at an even higher risk for both arterial and venous thrombotic events.

Pregnancy is not contraindicated in patients with ET. The outcome of pregnancy in patients with ET has recently been the subject of intense investigation. The rate of having a successful pregnancy is 61% compared with an 85% to 90% rate in normal women. The rate of spontaneous abortions ranges from 39% to 44% compared

Table 68-2 Risk Stratification in Essential Thrombocythemia Based on Thrombotic Risk*

Risk Category	Age >60 Years or History of Thrombosis	Cardiovascular Risk Factors
Low	No	No
Intermediate	No	Yes
High	Yes	Yes

Data from Finazzi G, Barbui T: Risk-adapted therapy in essential thrombocythemia and polycythemia vera. *Blood Rev* 19:243, 2005.
*Cardiovascular risk factors: hypertension, hypercholesterolemia, diabetes, smoking, and congestive heart failure. Extreme thrombocytosis (platelet count $>1500 \times 10^9$/L) is a risk factor for bleeding. Its role as a risk factor for thrombosis in essential thrombocythemia is uncertain.

with the miscarriage rate of 10% to 15% in normal pregnancies. Loss of the fetus late in the pregnancy is also more common in women with ET than in those without ET (5%–9.6% versus 0.5%). Placental infarction is often responsible for intrauterine fetal growth retardation (5%). Abruptio placenta has been reported in 3.6% of cases, a rate that is higher than that observed in the general population (1%). Major thrombotic episodes occur in 3% of these pregnancies while major bleeding episodes occur in 2% of cases. These rates are higher than that observed in the overall population of pregnant women.[18] The average platelet count at the beginning of pregnancy in patients with successful pregnancies was 1010×10^9/L, and it was 977×10^9/L among those with an unsuccessful outcome; thus the baseline platelet count is not predictive of pregnancy outcome. ET patients with the *JAK2V617F* mutation have been reported to be at a higher risk of developing complications with pregnancy. During the second trimester, a spontaneous decline in platelet counts was reported, reaching a nadir of 599×10^9/L. This decrease in platelet numbers seems larger than the reduction observed in normal pregnancies, which has been attributed to an increase in plasma volume. The mechanism for this reduction in platelet numbers is not known but could involve placental or fetal production of a factor that downregulates platelet production. In the postpartum period, the platelet counts return to their earlier levels, and rebound thrombocytosis may occur in some patients. This is thought to increase the probability of vascular complications during this period to a level similar to that observed in other conditions of thrombophilia.

In the large majority of cases, the fetal losses in pregnant ET women occur during the first trimester. In one series, 65% of the miscarriages occurred in 17% of women. Thus a previous history of spontaneous abortion may be the greatest risk factor for the development of subsequent spontaneous abortions.

Physical examination findings are relatively unremarkable in patients with ET. Most patients are not severely ill at diagnosis, with a median Karnofsky score of 90% being reported in one series. Splenomegaly is detectable in 40% to 50% of patients, and approximately 20% have hepatomegaly. During the course of the disorder, a further increase in the degree of hepatosplenomegaly may be observed in patients who are developing post-ET MF. Recently, skin manifestations of the MPN have been reported to be relatively common, ranging from paraneoplastic lesions, including vascular, neutrophilic plaques, and unexplained dermatoses. Rarely, vascular changes result in microcirculatory flow abnormalities, leading to a vasculities resulting in classic purpura that may progress to skin necrosis. This should be distinguished from leg ulcers that occur in patients being treated with hydroxyurea. Occasionally, patients also develop pyoderma gangrenosum or Sweet syndrome.

LABORATORY MANIFESTATIONS

The hallmark of ET is a sustained and unexplained elevation of the platelet count (≥450 × 109/L). The level of thrombocytosis required for the diagnosis is arbitrarily determined, the range being 450 to greater than 1000 × 109/L.[3] Accompanying leukocytosis is a common finding. A leukoerythroblastic blood picture, as well as teardrop-shaped RBCs are not features of ET but are suggestive of an early form of MF. Mild eosinophilia (>400/mm^3) and basophilia (>100/mm^3) have been reported in more than one-third of patients.

The most common morphologic abnormalities are variations in RBC size and shape and the presence of megathrombocytes (Fig. 68-3). The BM is usually normocellular or slightly hypercellular without a significant increase in granulopoiesis or erythropoiesis. Increased numbers of enlarged megakaryocytes with hyperlobulated or deeply folded nuclei that cluster in small groups along sinuses are the hallmarks of ET (see Fig. 68-3). Reticulin fibrosis is not significantly evident. A great deal of controversy currently surrounds distinguishing "true ET" from an early prefibrotic form of MF in which the BM is characteristically hypercellular with pronounced proliferation of granulocytes and reduced erythroid precursors. The megakaryocytes are increased in number but are loosely clustered or located along the endosteal bone surface. The megakaryocytes contain hyperchromatic, hypolobulated bulbous, or irregularly folded nuclei with an abnormal nuclear-to-cytoplasmic ratio. The histopathologic criteria for this form of PMF have been combined with clinical criteria (minor criteria) by the World Health Organization (WHO).[19] Two minor criteria are required to make a diagnosis of early PMF, including a leukoerythroblastic blood picture, increased serum LDH, anemia, and splenomegaly (Table 68-3). These minor criteria are important because the diagnosis of early PMF cannot be made without their fulfillment according to WHO criteria. Based on the 2008 WHO Diagnostic Criteria, the presence of modest BM reticulin fibrosis excludes the diagnosis of ET but is supportive rather of a diagnosis of an early form of MF. By contrast, the diagnostic criteria for ET defined by the British Committee for Standards in Hematology still classifies patients with grade 2 reticulin fibrosis on a scale of 0 to 4 as having ET. These two sets of diagnostic criteria are provided in Table 68-3 and are of importance because their implementation determines who one classifies as having "true" ET or an early form of MF. Although select hematopathologists can reproducibly distinguish ET from the early prefibrotic form of MF, it remains uncertain whether this distinction is broadly applicable. In fact, in one study of six European hematopathologists analyzing BM biopsies from 102 nonfibrotic patients with sustained thrombocytosis, in more than 50% of cases the classification of individual cases was not

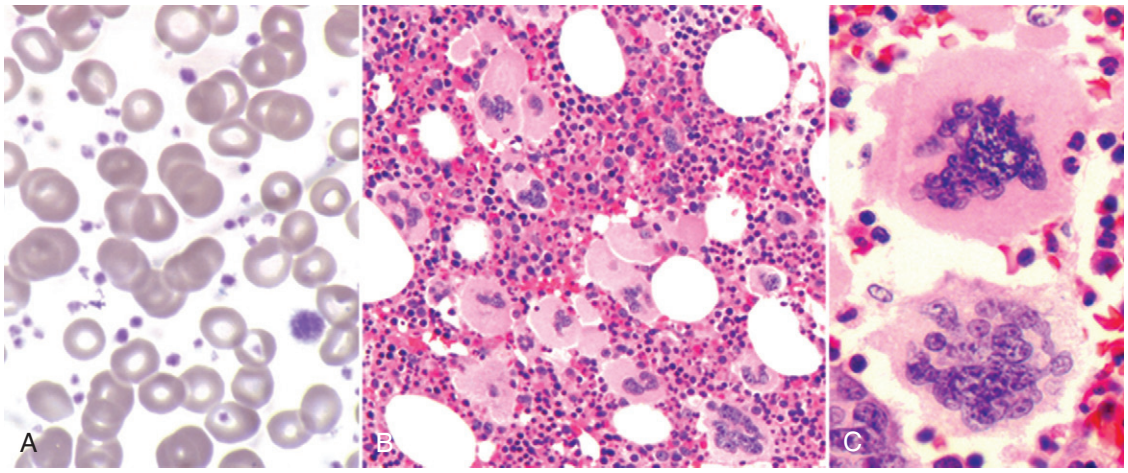

Figure 68-3 ESSENTIAL THROMBOCYTHEMIA (ET): PERIPHERAL BLOOD SMEAR AND BONE MARROW BIOPSY. The peripheral blood smear in ET shows a marked thrombocytosis with anisocytosis (varying sizes) of the platelets **(A).** The bone marrow **(B)** is hypercellular and exhibits a marked proliferation of large and giant megakaryocytes in loose clusters with other hematopoietic elements in the background. The large megakaryocytes **(C)** tend to be extensively lobulated.

Table 68-3 Proposed Revised World Health Organization Criteria for the Diagnosis of Primary Myelofibrosis and Essential Thrombocythemia and British Committee for Standards in Hematology Criteria for Diagnosis of Essential Thrombocythemia

Proposed Revised WHO Criteria for Primary Myelofibrosis

Major Criteria

1. Presence of megakaryocyte proliferation and atypia,* usually accompanied by either reticulin or collagen fibrosis or in the absence of significant reticulin fibrosis, the megakaryocyte changes must be accompanied by an increased BM cellularity characterized by granulocytic proliferation and often decreased erythropoiesis (i.e., prefibrotic cellular phase disease)
2. Not meeting WHO criteria for PV,† CML,‡ MDS,§ or other myeloid neoplasm
3. Demonstration of JAK2617V->F or other clonal marker (e.g., MPL515W->L/K) or in the absence of a clonal marker, no evidence of BM fibrosis caused by underlying inflammatory or other neoplastic diseases‖

Minor Criteria

1. Leukoerythroblastosis¶
2. Increase in serum LDH level¶
3. Anemia¶
4. Palpable splenomegaly¶

Diagnosis requires meeting all three major criteria and two minor criteria.

BM, Bone marrow; *CML,* chronic myeloid leukemia; *LDH,* lactate dehydrogenase; *MDS,* myelodysplastic syndrome; *PV,* polycythemia vera; *WHO,* World Health Organization.
*Small to large megakaryocytes with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and sense clustering.
†Requires the failure of iron replacement therapy to increase hemoglobin level to the PV range in the presence of decreased serum ferritin. Exclusion of PV is based on hemoglobin and hematocrit levels, and RBC mass measurement is not required.
‡Requires the absence of *BCR-ABL*.
§Requires absence of dyserythropoiesis and dysgranulopoiesis.
‖Secondary to infection, autoimmune disorder or other chronic inflammatory condition, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies. It should be noted that patients with conditions associated with reactive myelofibrosis are not immune to primary myelofibrosis, and the diagnosis should be considered in such cases if other criteria are met.
¶Degree of abnormality could be borderline or marked.

Proposed Revised World Health Organization Criteria for Essential Thrombocythemia

1. Sustained platelet count ≥450 × 10^9/L*
2. BM biopsy specimen showing proliferation mainly of the megakaryocytic lineage with increased numbers of enlarged, mature megakaryocytes; no significant increase or left shift of neutrophil granulopoiesis or erythropoiesis
3. Not meeting WHO criteria for PV,† PMF,‡ CML,§ MDS,‖ or other myeloid neoplasm
4. Demonstration of *JAK2V617F* or other clonal marker or in the absence of a clonal marker, no evidence for reactive thrombocytosis¶

Diagnosis requires meeting all four criteria.

From Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: Recommendations from an ad hoc international expert panel. *Blood* 110:1092, 2007.
BM, Bone marrow; *CML,* chronic myeloid leukemia; *MDS,* myelodysplastic syndrome; *PV,* polycythemia vera; *WHO,* World Health Organization.
*During the workup period.
†Requires the failure of iron replacement therapy to increase hemoglobin level to the PV range in the presence of decreased serum ferritin. Exclusion of PV is based on hemoglobin and hematocrit levels, and red blood cell mass measurement is not required.
‡Requires the absence of relevant reticulin fibrosis, collagen fibrosis, peripheral blood leukoerythroblastosis, or markedly hypercellular BM for age accompanied by megakaryocyte morphology that is typical for PMF—small to large with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and dense clustering.
§Requires the absence of *BCR-ABL*.
‖ Requires absence of dyserythropoiesis and dysgranulopoiesis.
¶Causes of reactive thrombocytosis include iron deficiency, splenectomy, surgery, infection, inflammation, connective tissue disease, metastatic cancer, and lymphoproliferative disorders. However, the presence of a condition associated with reactive thrombocytosis does not exclude the possibility of ET if the first three criteria are met.

British Committee for Standards in Hematology Criteria for Diagnosis of Essential Thrombocythemia

Requires A1-A3 or A1+A3-A5
A1: Sustained platelet count >450 × 10^9/L
A2: Presence of an acquired pathogenetic mutation (e.g., in *JAK2* or MPL)
A3: No other myeloid malignancy, especially PV, PMF, CML, or MDS
A4: No reactive cause for thrombocytosis and normal iron stores
A5: BM aspirate and trephine biopsy showing increased megakaryocyte numbers displaying a spectrum of morphology with predominant large megakaryocytes with hyperlobated nuclei and abundant cytoplasm

From Harrison et al: Br. J Haemotol 149:352, 2010.
BM, Bone marrow; *CML,* chronic myeloid leukemia; *JAK2,* Janus kinase 2; *MDS,* myelodysplastic syndrome; *MPL,* thrombopoietin receptor; *PMF,* primary myelofibrosis; *PV,* polycythemia vera.

reproducible or fell into the category of unclassifiable MPN.[20] In 70% to 80% of ET patients, iron stores were present in the BM, albeit at reduced levels. Almost all patients have normal serum ferritin levels. The absence of iron stores in 30% of patients may merely be an epiphenomenon of a chronic MPN and not truly reflective of an iron deficiency state. Platelet aggregation study results are frequently abnormal, most often demonstrating an impaired aggregation response to epinephrine, ADP, and collagen but not to arachidonic acid and ristocetin. Spontaneous platelet aggregation has been reported to occur frequently in such patients, but this has not been a universal finding.

Approximately 25% of patients with ET have been reported to have elevated uric acid levels at diagnosis. The average value of the serum potassium at diagnosis is usually within the normal range, although 23% of patients have been reported to have pseudohyperkalemia, and caused by the degranulation of platelets when in vitro

clotting releases potassium. Both excessive numbers of RBCs and leukocytes can also be associated with these phenomena. The pseudohyperkalemia can be documented by measuring plasma instead of serum potassium levels and the lack of electrocardiographic findings associated with true hyperkalemia. Pseudohypoxemia has also been observed in ET patients with extreme degrees of thrombocytosis. Acquired von Willebrand syndrome is associated almost uniformly with a platelet count greater than 1500×10^9/L, a prolonged bleeding time, a normal factor VIII coagulant activity, and a von Willebrand antigen level but a decreased von Willebrand factor–ristocetin cofactor activity and collagen binding activity, as well as a decrease or absence of large von Willebrand factor multimers simulating a type II von Willebrand disorder. The enhanced thrombotic risk of ET patients has been associated with a reduction in the concentration of one of the natural anticoagulants, including protein S, antithrombin III protein C, and resistance to activated protein C. These studies indicate that such a genetic deficiency of one of the natural anticoagulants might further contribute to the thrombotic tendency of patients with ET. The serum vitamin B_{12} level can be increased in 25% of cases.

In ET, BM karyotypes are characteristically normal. The absence of the Philadelphia chromosome and the *BCR/ABL* rearrangement excludes the diagnosis of chronic myeloid leukemia (CML). The Philadelphia chromosome or the *BCR/ABL* rearrangement that is seen in patients with CML must be searched for in patients who present with a high platelet count because of the observation that thrombocytosis may be the initial laboratory abnormality in patients with CML. Rare patients share two molecular markers of MPNs (*JAK2V617F* and *BCR/ABL*). Because the prognosis and management for ET and CML are very different, it is important to rule out CML as the cause of the elevation in platelet numbers. Aneuploidy is seen in the minority of cases at diagnosis. In fact, ET is associated with a definite chromosomal abnormality in only 7.8% of cases, but with disease progression, there is an increased risk of aneuploidy. Specific chromosome abnormalities associated with ET have not been described, but abnormalities observed in PV and PMF as well as in myelodysplastic syndrome (MDS) such as trisomy 1q, deletions of 5q, 13q and 20q, trisomy 8 as well as monosomal karyotypes have been reported. Many nonspecific chromosomal rearrangements have also been observed such as a complex karyotype, presence of a marker chromosome, and unusual translocations. Molecular cytogenetic studies in ET have not been performed extensively. In one reported study, addition of fluorescence in situ hybridization (FISH) increased detection of chromosomally abnormal clones by 15%. But in 21 patients studied with oligoarray comparative genomic hybridization, one additional patient with deletion 13q was identified compared with conventional cytogenetics. In 12 pediatric ET patients, chromosomal abnormalities were not detected. Leukemic transformation of ET is characterized by development of an abnormal karyotype in 60% to 100% of patients. Consistent chromosomal abnormalities associated with ET progression in *JAK2V617F*-positive patients are der(1)t(1;9) and der(1;7)(q10;p10). Of the eight reported ET patients with der(1;7), five received previous chemotherapy (chlorambucil, hydroxyurea, pipobroman, melphalan, cytosine arabinoside, anthracycline), and six transformed to acute leukemia. Although der(1)t(1;9) is a consistent nonrandom rearrangement associated with de novo PV and with PV progression, four ET patients had der(1)t(1;9) with different breakpoints (p13;p13) and (q10;p10). In ET, similar to PV, PMF, and other myeloid disorders, formation of trisomy 1q alone or subsequent formation of jumping +1q translocations should be considered a clonal marker associated with disease progression or transformation to AML. As has been previously mentioned, approximately 50% of ET patients are *JAK2V617F* positive with only 4% having a high allele burden. Approximately 3% to 5% of patients have activating MPL mutations.

DIFFERENTIAL DIAGNOSIS

Thrombocytosis is a common finding. There are numerous causes of primary, secondary, and spurious forms of thrombocytosis. A listing of the conditions that can lead to thrombocytosis is provided in Table 68-4. Primary thrombocytosis includes both acquired and hereditary forms. In acquired forms of primary thrombocytosis, the genetic abnormalities are present exclusively in hematopoietic cells, but in the hereditary forms, these underlying defects can be detected in both somatic and germ line cells and are inherited. The discovery of *JAK2* and MPL mutations has provided definitive diagnostic tools with which to diagnose the MPNs, including ET. These mutations, however, can be found only in about half of ET patients. Hence, it is reasonable to consider *JAK2V617F* analysis and a search for a mutation in MPL when evaluating patients with otherwise unexplained thrombocytosis. A positive test result indicates an underlying MPN. However, further investigations, including a BM biopsy (see Table 68-3) as well as a cytogenetic analysis, are still required to differentiate ET from the other chronic MPNs as well as from myelodysplastic disorders presenting with thrombocytosis, such as the 5q– syndrome and refractory anemia with ringed sideroblasts associated with thrombocytosis (RARS-T) (see Table 68-4) and early forms of PMF.

For those patients who present with thrombocytosis who are *JAK2* negative, the first step in determining the cause of thrombocytosis is to exclude reactive forms of thrombocytosis.[21] The causes of secondary or reactive forms of thrombocytosis are numerous, but the most common causes are infection, inflammation, hemolysis, severe exercise, malignancy, hyposplenism, and other causes of an acute phase response (see Table 68-4). In a hospital population, patients with extreme thrombocytosis ($>1000 \times 10^9$/L) are not particularly rare in adult or pediatric patient populations. Examination of the blood smear is important to avoid confusion with so-called pseudothrombocytosis. This occurs in a number of conditions in which platelet-sized particles of red or white blood cell fragments (CLL, TTP, hemoglobin H disease), schistocytes, microspherocytosis, and cryoglobulinemia are erroneously enumerated as platelets by automatic particle counters. Confirmation of increased numbers of platelets by examination of the peripheral smear will avoid misdiagnosis and unnecessary clinical evaluation.

Table 68-4 Conditions Associated With Thrombocytosis

Primary Thrombocytosis
Malignancies
Essential thrombocythemia
Polycythemia vera
Primary myelofibrosis
Chronic myeloid leukemia
Refractory anemia with ringed sideroblasts and thrombocytosis
Chronic myelomonocytic leukemia
MDS/MPN overlap
Familial thrombocythemia (inherited mutations in thrombopoietin or thrombopoietin receptor)
Secondary (Reactive) Thrombocytosis
Blood loss or iron deficiency
Infection
Inflammation
Disseminated malignancy
Hemolysis
Drug therapy
Hyposplenism
Cytokine administration
Spurious Thrombocytosis
Schistocytes
Cytoplasmic fragmentation of neoplastic cells
Cryoglobulinemia
Bacteria

MDS, Myelodysplastic syndrome; *MPN,* myeloproliferative neoplasm.

Whereas reactive thrombocytosis accounts for more than 88% to 97% of cases, thrombocytosis caused by an MPN accounts for only a minority of cases. Reactive thrombocytosis is more common in all age groups except those in the eighth decade and older. A significant number of patients with reactive thrombocytosis have platelet counts greater than 1000×10^9/L. It is therefore impossible to distinguish between reactive thrombocytosis and thrombocytosis caused by an MPN based solely on the degree of thrombocytosis. Thrombotic and hemorrhagic events infrequently occur in patients with reactive thrombocytosis. These findings are in contrast to the enhanced risk of these two complications in patients with ET. This relatively high frequency of extreme thrombocytosis in an acute care hospital emphasizes the need for caution in making a diagnosis of ET (Table 68-5). A number of groups have shown that reactive thrombocytosis may be a consequence of the elaboration of known cytokines in response to the underlying inflammatory or neoplastic disorder and are accompanied by an elevated erythrocyte sedimentation rate or a high C-reactive protein (CRP). Elevated levels of IL-1, IL-6, GM-CSF, G-CSF, and thrombopoietin have been detected in such patient populations and frequently in individuals with thrombocytosis caused by an underlying MPN. Elevation of thrombopoietin levels has not only been found in patients with reactive thrombocytosis but also in patients with ET. IL-6–induced thrombocytosis is mediated in part by secondary thrombopoietin production by the liver in inflammatory disorders and malignant diseases. Thus as opposed to erythropoietin levels being helpful in differentiating primary from secondary causes of erythrocytosis, the level of thrombopoietin cannot be used to differentiate ET from secondary causes of thrombocytosis. CRP is an acute phase reactant, the hepatic synthesis of which is mediated by IL-6. CRP levels are high in patients with high levels of IL-6. In one series, whereas 81% of patients with reactive thrombocytosis had elevated IL-6 or CRP levels, patients with uncomplicated thrombocytosis secondary to an MPN had undetectable IL-6 levels. Low levels of both IL-6 and CRP are strongly indicative of the thrombocytosis being the consequence of an underlying MPN.

Both familial forms of thrombocytosis and thrombocytosis that accompanies hematologic malignancies are examples of primary thrombocytoses. The MPNs are characterized by clonal hematopoiesis, but in the familial forms of thrombocytosis, hematopoiesis is polyclonal. An abnormality of thrombopoietin production or of the thrombopoietin receptor has been documented to be the basis of these inherited disorders leading to thrombocytosis.

Four different mutations have been reported in which excessive thrombocytosis has been attributed to increased thrombopoietin production. A Dutch family with 11 family members and a Japanese family with eight family members were reported with a hereditary form of thrombocytosis that was inherited as an autosomal dominant. The thrombopoietin receptor in the Dutch family was normal, yet there was a G-to-C transversion in the splice donor site of intron 3 of the thrombopoietin gene. All of the affected members of the Dutch family were shown to have elevated thrombopoietin levels. In this family, a point mutation in the thrombopoietin gene was believed to lead to systemic overproduction of thrombopoietin, leading to a familial form of thrombocytosis. This was the first example of a human disease caused by increased efficiency of mRNA production. Actually, the translation of full-length thrombopoietin is almost completely inhibited by the presence in the 5′ untranslated region of seven AUG codons, which create seven upstream reading frames (uORFs). These uORFs are potent inhibitors of translation, and mutations in this area cause thrombocytosis by eliminating the normal physiological inhibition of thrombopoietin mRNA translation. Three additional families with thrombocytosis caused by a similar genetic mechanism have been identified.

Another form of familial thrombocytosis has been attributed to germ line mutations of MPL (MPL-S505N, MPL-K39N, and MPL-P106L). MPL-S505N was first described in a Japanese pedigree of familial thrombocytosis that is inherited in an autosomal dominant fashion. This disorder has been attributed to a dominant-positive activating mutation of the cellular receptor of MPL. Eight additional Italian families with thrombocytosis and MPL-S505N have been identified.

A polymorphism of the thrombopoietin receptor (MPL Baltimore, MPL-K39N) that is accompanied by thrombocytosis has also been described. This polymorphism is caused by a single nucleotide substitution that results in a lysine to asparagine (K39N) substitution in the ligand-binding domain of MPL. The polymorphism occurs exclusively in African Americans and appears to have an autosomal dominant pattern of inheritance with incomplete penetrance because some heterozygotes have normal platelet counts but others have thrombocytosis. Approximately 7% of African Americans are heterozygous for MPLK39N. The mutation in the homozygous state is associated with extreme thrombocytosis with a reduced expression of platelet MPL, which has been proposed to affect the receptor's ability to bind thrombopoietin, resulting in its reduced clearance and increased stimulation of megakaryocytopoiesis. MPL-P106L is another mutation associated with familial thrombocytosis that has been found in 6% of Arabs.

Subjects with familial forms of thrombocytosis are characteristically diagnosed at earlier ages than patients with ET. These disorders were initially considered to be associated with a benign clinical course, but follow-up of such families for longer periods of time has corrected this misperception. Overall, 23 members of a Dutch and a Polish family with a form of thrombocytosis attributed to excessive thrombopoietin production were shown to have similar thrombotic and hemorrhagic complications as individuals with ET. Also, these family members experienced vasomotor symptoms, including erythromelalgia and Raynaud phenomena, that responded to aspirin therapy but not hydroxyurea therapy. Furthermore, many of these patients developed splenomegaly as well as BM histopathologic findings that resemble an MPN, including BM hypercellularity, clustering of megakaryocytes, and a mild increase of BM fibrosis. Surprisingly, more prolonged follow-up of members of the Dutch family have revealed progression to symptomatic MF in one individual and progression to acute leukemia in a second family member. The patient with acute leukemia had not received any chemotherapeutic agents, and evaluation of the strength of the relationship between this high thrombopoietin condition and the development of acute leukemia requires further investigation of these families. Similarly, patients with the activating mutation of MPL, MPL-S505N also have a high incidence of major thrombotic events, including stroke, myocardial infarction, and Budd-Chiari syndrome. In adult patients, overt BM reticulin and collagen fibrosis associated with mild reductions in hemoglobin levels have been observed, but no differences in platelet counts, incidence in thrombotic episodes, or splenomegaly have been

Table 68-5 Clinical and Laboratory Features Helpful in Distinguishing Essential Thrombocythemia from Reactive Thrombocytosis* (Revised)

†Erythroid colonies.

observed when one compares these individuals with ET patients. In women with MPL-S505N, hematopoiesis is polyclonal, and the mutation is observed not only in hematopoietic tissues but also other somatic tissues. Family members who are affected by this mutation appear to have a significantly shorter survival time than nonaffected family members who did not have thrombocytosis, with affected individuals dying most frequently of thrombotic events or complications of MF. By contrast, individuals with either MPL-K39N or MPL-P106L, which both involve the extracellular domain of MPL affecting its ability to bind thrombopoietin, do not have an increased risk for thrombosis, splenomegaly, or BM fibrosis. Because the median age of diagnosis of patients with these familial forms of thrombocytosis is 17 years, these disorders should be carefully considered in all *JAK2V617F-, MPLW515L-,* and *MPL515K*-negative children with multiple family members with thrombocytosis.

Table 68-3 outlines the recently updated WHO and British Committee for Standards in Hematology criteria for the diagnosis of ET that incorporates JAK2V7617F and MPL mutational analyses. RBC mass and plasma volume studies, if available, are sometimes helpful in differentiating between *JAK2V617F*-positive ET with borderline elevated hematocrits from patients with PV, but such patients likely represent a continuum of evolution of a *JAK2V617F*-positive hematologic malignancy. BM karyotypic analysis or studies for the *BCR-ABL* fusion gene are imperative in every patient to exclude the diagnosis of CML or to detect another clonal hematologic malignancy. This step is necessary because the natural history of these disorders is very different, and early therapeutic intervention with specific medical therapy for CML, such as with imatinib, dasatinib, or nilotinib, is essential.

Occasionally, ET might be distinguished from refractory anemia with ring sideroblasts and thrombocytosis (RARS-T), which has been recognized by the WHO classification of hematologic malignancies. These patients present with thrombocytosis that is associated with a moderate to severe anemia and frequently splenomegaly. Their BMs are characterized by the morphologic features of ET and the presence of more than 15% ringed sideroblasts. This entity likely represents a heterogeneous, poorly defined disorder that includes a spectrum of conditions sharing features of an MPN and a myelodysplastic disorder. This entity is associated with *JAK2V617F* in 58% of reported patients and a MPLW515 mutation in 7% of reported patients. Occasional patients with thrombocytosis and increased ringed sideroblasts but without anemia have also been described. Patients with RARRS-T have a similar prognosis as ET patients. RARS-T has been recently shown to be associated with somatic mutations of *SF3B1,* a gene encoding a core component of the RNA splicing machinery.[22] In RARS-T, the allele burden of mutant *SF3B1* ranges from 17% to 62%. The *SF3B1* mutations are associated with expanded but ineffective erythropoiesis. RARS-T therefore likely results from a combination of *SF3B1* and *JAK2* or *MPL* mutations.[23] About 25% of patients with RARS-T have wild-type *SF3B1,* suggesting that other molecular defects can be associated with RARS-T.

Because patients with early forms of MF frequently present with thrombocytosis, this form of PMF can frequently be difficult to distinguish from ET. This early form of PMF was previously referred to as a prefibrotic form of PMF. In the prefibrotic phase of PMF, nucleated RBCs, teardrop-shaped RBCs, immature myeloid cells, and megathrombocytes are observed in the peripheral blood. In the BM biopsy, the megakaryocytes are markedly abnormal, a morphologic finding that is helpful in distinguishing this entity from ET. In prefibrotic PMF, the megakaryocytes often appear in clusters adjacent to the sinusoids; deviations in the nuclear cytoplasmic ratio in the megakaryocytes are observed with abnormal patterns of chromatin clumping, and plump clouds similar to a balloon-shaped lobulation of the nuclei are observed associated with minimal fibrosis or even absent reticulin fibrosis during this stage of PMF.

The presence of clonal hematopoiesis, at least in one lineage, quickly establishes the diagnosis of ET. Unfortunately, techniques to study clonality are currently not widely available and are restricted to the evaluation of female patients. Such studies may be particularly useful in young female patients with thrombocytosis. Probes for a variety of genes on the X chromosome can be informative for clonal analysis of blood cell production in more than 72% of female Americans. In such patients, analysis of restriction fragment length polymorphisms can be used to establish a pattern of clonal hematopoiesis, which is indicative of a hematologic malignancy and establishes the diagnosis of ET in a young female patient with thrombocytosis who is *JAK2V617F* negative. Polyclonal hematopoiesis is found in all cases of reactive and familial thrombocytosis. Polyclonal hematopoiesis, however, does not exclude the diagnosis of ET because in several series, almost one-third of patients who met the clinical criteria for ET had polyclonal hematopoiesis in all studied lineages. The biogenesis of this polyclonal form of ET is poorly understood. Initial studies, however, have suggested that women with polyclonal hematopoiesis may have fewer thrombotic complications than those with clonal hematopoiesis.

A number of diagnostic tests, including splenic volume estimates using ultrasound evaluations and assays of BM progenitor cells (erythroid or megakaryocyte), have been suggested as useful means of differentiating reactive thrombocytosis from ET (see Table 68-5). Insufficient numbers of patients, as well as a lack of long-term follow-up, make it impossible to assess the clinical value of such tests. As outlined earlier, the most important step in improving the diagnosis of ET has been the identification of the *JAK2V617F* mutation in about 50% of patients with ET. The current availability of this relatively simple molecular test makes it easier to establish the diagnosis of ET, although the utility of the test is limited by suboptimal negative predictive value and lack of diagnostic specificity.

At times, it is impossible to define the cause of an individual patient's thrombocytosis. In an asymptomatic patient, the resolution of this problem is easy: one should simply provide follow-up and determine whether the degree of thrombocytosis increases. If additional clues to the cause of the thrombocytosis are subsequently revealed, a diagnosis will become apparent. In a patient with thrombohemorrhagic difficulties, one must make a presumptive diagnosis of the cause of the thrombocytosis and then, after weighing the benefits versus the risks of various treatment plans, determine whether reduction of platelet numbers or simple observation is indicated. Some reassurance is provided by reports of larger cohorts of patients, each with platelet counts of greater than 1000×10^9/L, have been followed for years. Virtually none of the patients with reactive thrombocytosis developed a cerebrovascular accident, thrombophlebitis, or a peripheral arterial thrombosis.

PROGNOSIS

The probability that a patient with ET will survive 10 years ranges from 64% to 80%. In a large study from Spain with extensive follow-up, there was no substantial difference between the probability of survival of patients with ET and that of a control population. However, a study of 322 consecutive patients seen at the Mayo Clinic and followed for a median follow-up of 13.6 years showed a different pattern. Survival of patients with ET was similar to that of the control population during the first decade of disease, but the survival became significantly worse thereafter. Multivariable analysis identified an age at diagnosis of 60 years or older, leukocytosis, tobacco use, and diabetes mellitus as independent predictors of poor survival. The risk of developing leukemia or MF was low in the first 10 years (1.4% and 3.8%, respectively) but increased substantially in the second (8.1% and 19.9%, respectively) and third (24.0% and 28.9%, respectively) decades of the disease. The presence of the *JAK2V617F* mutation did not influence either survival or the rate of leukemic transformation. The rate of leukemic transformation was, however, higher in patients with platelet counts above 1000×10^9/L and abnormal hemoglobin levels. The development of MF was heralded by the appearance of immature myeloid precursors and dacryocytes in the blood smear and increased serum lactate dehydrogenase levels followed by a reduction in platelet numbers and progressive splenomegaly. This does not represent an instance of misdiagnosis but rather the natural evolution of the underlying hematologic malignancy. In addition, some

patients, especially women who are iron deficient, may have their erythrocytosis masked and thus may truly have PV, although with the finding of an elevated platelet count, a diagnosis of ET may have been made or patients with *JAK2V617F* positive are known not infrequently to evolve to a picture that resembles PV as has been previously discussed.

A major determinant of the prognosis of a patient with a presumptive diagnosis of ET depends on the discrimination of whether such patients actually have true ET or an early form of MF based on histopathologic and clinical criteria adopted by the WHO (see Table 68-3).[24] Although some investigators believe that these histopathologic criteria cannot be widely implemented because of interobserver differences, the recent examination of large numbers of cases in a blinded fashion has shed some light on the clinical significance of the implementation of the WHO criteria. In a group of 891 patients with a prior diagnosis of ET with BM biopsies evaluated retrospectively histopathologically, 16% were reclassified as having an early or prefibrotic form of MF. Thrombosis rates and *JAK2V617F* positivity were similar in the two groups. However, patients with an early form of MF had higher leukocyte counts, lower hemoglobin levels, higher platelet counts, higher lactic dehydrogenase levels, greater numbers of circulating $CD34^+$, cells and a greater incidence of palpable splenomegaly than patients with true ET. Survival was reported to be significantly inferior for those patients with the early form of PMF compared with patients with histopathologically validated ET (Fig. 68-4). In one series with a median follow-up of approximately 7 years, the median survival of patients with ET ranged from 16 to 21 years, and the survival of the patients with the early form of MF ranged from 10.8 to 14.4 years with the majority of deaths being attributed to progression to overt PMF and acute leukemia. Although the patients with ET enjoyed a more favorable outcome, the 15-year cumulative incidences of overt MF and acute leukemia were still 9.3% and 2.1%, respectively, emphasizing the seriousness of this diagnosis, especially in younger patients.

Death of ET patients predominantly results from thrombotic complications, but transformation to AML is an important cause of mortality. The phenotype of the blast cell can be myeloid, myelomonocytic, megakaryocytic, of mixed lineage, or even lymphoblastic. According to the data mentioned earlier, the risk of patients with ET transforming into acute leukemia is greater than that of normal individuals. This is a phenomenon shared with the other MPN. The risk of developing acute leukemia after treatment with hydroxyurea alone increases only slightly (3%–4%), but the sequential use of hydroxyurea with other cytotoxic agents, such as busulfan or pipobroman, significantly increases the risk of developing a secondary leukemia.

The development of acute leukemia is associated with a deletion of the short arm of chromosome 17, which is most frequently deleted in hydroxyurea-treated patients, but a trisomy of the long-arm of chromosome 1 and monosomy 7q has been observed in patients treated with pipobroman. These cytogenetic abnormalities are believed to be induced by the use of these chemotherapeutic agents. The median survival after the development of myelodysplasia or leukemic transformation is 4 months. Acute leukemia, which develops after ET, is frequently refractory to standard induction chemotherapy but has been recently reported to be responsive to hypomethylating agents, including 5-azacytidine and decitabine. Because allogeneic stem cell transplantation can be curative, rapid referral to a transplant center is recommended if the patient has an appropriate performance status and an allogeneic stem cell donor is available.

THERAPY

The goal in treating patients with ET is to prevent additional thrombotic and hemorrhagic events without increasing the risk of transformation to post-ET MF or AML. Both age (>60 years of age) and a history of a prior thrombosis are predictors of a patient developing additional thrombotic events during follow-up (Table 68-6). Other predictors of cardiovascular morbidity include a history of smoking, hypertension, diabetes mellitus, and congestive heart failure and a white blood cell count greater than 11 × 109/L. Ironically, patients with platelet counts greater than 1000 × 109 /L have a lower risk of

developing an arterial thrombosis. These parameters have been widely used by clinicians to stratify ET patients according to their risk for developing additional thrombotic events. Such stratification strategies have been used to make decisions on the need to use agents that are capable of reducing platelet counts. It is important to emphasize that such risk factors have been identified based on retrospective analyses of registries of ET patients that have largely not been created using modern molecular and histopathologic diagnostic tools. Using such patient stratification strategies, patients have been placed into high-, intermediate-, or low-risk groups based on their predicted risk of developing an additional life-threatening thrombotic event. This strategy is uniformly implemented throughout Europe and North America. The benefit of this strategy is based on a single clinical trial that indicated that the reduction of platelet numbers to less than 600 × 109/L with hydroxyurea therapy was associated with a reduction of developing additional thrombotic events compared with a control group (see Fig. 68-1). This study involved a total of 114 patients, and the median follow-up period was only 27 months.[25] Greater degrees of platelet suppression have not been shown to be associated with further reduction in the possibility of developing a thrombotic episode, which in hydroxyurea-treated high risk patients has been reported to be 1.66% patients per year. Although the implementation of such a strategy is widely accepted, it is important to be aware that this approach is not based on robust data that one associates with modern day evidence-based medicine. In fact, in several studies, an elevated leukocyte count of above 11 × 109/L has been more closely associated with the risk of developing additional thromboses than the degree of elevation of the platelet count. These conflicting reports in the literature among experts in this field makes it increasingly more difficult to be dogmatic about who to treat with platelet-lowering agents. The risk stratification of patients should not be ignored, and patients with a life-threatening thrombosis or disabling symptoms because of microcirculatory problems should receive drugs that lower the platelet count, but it seems somewhat robotic to treat every individual with ET older than 60 years of age with a similar strategy unless they have serious cardiovascular comorbidities. Obviously, if a patient of any age has excessive thrombocytosis and a thrombotic or hemorrhagic event, that patient must be treated, but for asymptomatic ET patients in so-called high-risk categories, the decision to embark upon a strategy including platelet-lowering agents is in reality a murky one that is more based on personal treatment decisions than volumes of data.

The treatment of asymptomatic low-risk patients with ET is controversial and remains largely problematic, yet greater insight into the management of such patients has recently been gained. Management of ET patients with life-threatening hemorrhagic or thrombotic episodes is more straightforward. Life-threatening thrombotic events require platelet pheresis in combination with the institution of myelosuppressive therapy. In this situation, immediate physical removal of large numbers of platelets is preferred because chemotherapeutic agents generally require 18 to 20 days before platelet counts can be reduced to normal levels. It is recommended to reduce the platelet count to 500,000/mm^3 by each platelet pheresis and suggested that achievement of such a goal requires the passage of two blood volumes over a 3- to 4-hour period.

Such a therapeutic approach has been used to treat acutely ill patients with problems, such as cerebrovascular accidents, myocardial infarction, transient ischemic attacks, or life-threatening gastrointestinal hemorrhage. Long-term platelet pheresis is an ineffective means of controlling thrombocytosis, presumably because of the rapid rate of production of platelets. Therefore, most clinicians begin by administering a chemotherapeutic agent that has a rapid onset of action, such as hydroxyurea at doses of 2 to 4 g/day, simultaneously with the institution of platelet pheresis. The dose of hydroxyurea requires close monitoring with appropriate reduction of dose to avoid excessive myelosuppression.

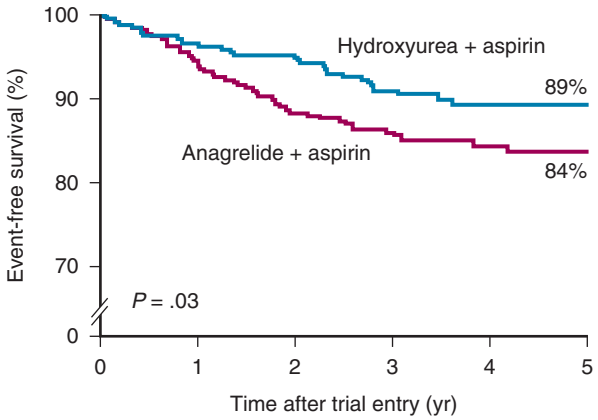
In patients found to have ET and who are clearly symptomatic and fall into the high-risk group, little controversy exists as to the need for lowering platelet numbers. The large number of thrombotic complications that occur in patients with ET who smoke points to the urgent need for these patients to stop smoking immediately. Most investigators try to normalize the platelet count or to reach a platelet count at which the symptoms of the high-risk patient resolve. Although major bleeding episodes requiring hospitalizations are rare, patients with extreme thrombocytosis (>1500 × 10^9/L), acquired von Willebrand syndrome, and history of hemorrhagic episode are clearly at risk for developing additional bleeding complications. These patients require reduction of the increased platelet numbers to the normal range with use of a variety of agents, including hydroxyurea, anagrelide, or INF-α. According to some authors, such patients should avoid exposure to aspirin even if they have hemorrhagic complications and thrombotic episodes simultaneously.

Another situation that requires treatment is discomfort caused by erythromelalgia or progression of erythromelalgia to frank gangrene. Such patients respond within days to low-dose aspirin therapy or platelet reduction therapy.

During the 1980s and 1990s, hydroxyurea became the drug of choice for the treatment of ET. The impetus for this practice was based on the knowledge that agents such as ^{32}P and alkylating agents such as melphalan and busulfan were leukemogenic. The popularity of the ribonucleoside reductase inhibitor, hydroxyurea, for the management of ET was due to the belief in the early 1970s that it was nonleukemogenic. Hydroxyurea can be administered at a dose of 15 mg/kg initially with adjustment of the dose to maintain a platelet count (at the least) below 600 × 10^9/L without inducing significant neutropenia. After the agent is started, frequent monitoring of blood counts is mandatory to avoid the development of neutropenia until the maintenance dose is determined. The use of this drug in a high-risk group of patients with reduction of platelet numbers to less than 600 × 10^9/L has resulted in reduction of thrombotic events compared with a control population. The reduction of platelet numbers to this level did not entirely eliminate the occurrence of additional thrombotic episodes.

Hydroxyurea use is associated with some toxicity, including dose-related neutropenia, nausea, stomatitis, hair loss, nail discoloration, and lower extremity and oral ulcerations as well as squamous cell carcinoma of the skin. Many of these problems resolve with withdrawal of the drug or dose reduction, but leg ulcers can be persistent, sometimes requiring skin grafting. These ulcers typically heal within 1 to 9 months of cessation of therapy. Such leg ulcers have been reported to occur in 9% of patients treated with hydroxyurea and are an indication for immediate discontinuation of therapy and elimination of any rechallenge with the drug. Hydroxyurea is also not universally successful in controlling the thrombocytosis; resistance to hydroxyurea has been reported in 11% to 17% of cases. The criteria for defining resistance or intolerance to hydroxyurea have been established by an International Working Group. They include a platelet count greater than 600 × 10^9/L after 3 months of at least 2 g/day of hydroxyurea (2.5 g/day in patients with a body weight >80 kg); platelet count greater than 400 × 10^9/L and WBC less than 2500/mm^3 or hemoglobin less than 10 g/dL at any dose of hydroxyurea; presence of leg ulcers or other unacceptable mucocutaneous manifestations at any dose of hydroxyurea; and hydroxyurea-related fever. In such situations, hydroxyurea can be substituted for (or combined with) other platelet-lowering agents. These criteria for hydroxyurea resistance are imperfect because they do not include the development of a thrombotic event while on therapy, which is the central goal of therapy. Whether such patients who develop a new thrombosis would benefit from use of another therapeutic agent has not been explored.

The risk of evolving to acute leukemia is extremely low in untreated ET patients. More recent prospective studies both in ET and PV have confirmed that hydroxyurea therapy is associated with a low incidence of leukemic transformation when used alone (<5%) and with long-term follow-up (≤14 years). However, the leukemic risk increased significantly when the drug is used before or after treatment with alkylating agents, particularly busulfan. One can conclude from these studies that hydroxyurea therapy alone is less leukemogenic than alkylating agents or P^{32} alone, but a small increased risk for the development of leukemia secondary to its use can not be



completely excluded. Of concern is the observation that a high proportion of the AMLs and myelodysplastic disorders occurring in ET patients treated with hydroxyurea alone have morphologic, cytogenetic, and molecular characteristics of the 17p deletion syndrome. These patients are reported to have a typical form of dysgranulopoiesis characterized by hypolobulated polymorphonuclear leukocytes with small vacuoles in neutrophils and p53 mutations.

An alternative to hydroxyurea is therapy with anagrelide. Data on the use of anagrelide in ET suggest that it is nonleukemogenic when used in patients with ET. When considering the risk-to-benefit ratio, one can conclude that hydroxyurea therapy is first-line therapy for ET patients at a high risk of developing an additional thrombosis, including those older than 60 years of age or with a history of a thrombotic episode or with significant other cardiovascular risk factors. Such nonleukemogenic drugs as INF-α, anagrelide, or pegylated INF appear to be good choices in symptomatic patients younger than 40 years of age.

Anagrelide is a member of the imidazo (2,1-b)quinazolin-2-1 series of compounds. When studied in humans, it was noted that anagrelide in small doses produced thrombocytopenia. The drug acts primarily by reducing megakaryocyte size and ploidy and decreasing megakaryocyte proliferation. Anagrelide therefore appears to lower platelet counts primarily by interfering with the development of megakaryocytes. Anagrelide suppresses megakaryocytopoiesis by selectively reducing the expression levels of GATA-1,FLI-1,NFE-2, and FOG-1 in cells belonging to the megakaryocytic lineage.[26] The effects of anagrelide do not involve thrombopoietin-mediated signal transduction events. GATA-1 and FOG-1 play critical roles in megakaryocytic differentiation. Anagrelide in low doses is effective in lowering the platelet count in 93% of patients. Most importantly, it is effective despite resistance to prior therapies. Resistance to anagrelide therapy has not been documented, but occasionally patients have been observed to require extraordinarily high doses to control the excessive thrombocytosis. The recommended initial dose is 0.5 mg orally two to four times a day. The dose should be increased by 0.5 mg/wk to control thrombocythemia. The dose of anagrelide should not exceed 10 mg/day or 2 mg/dose. Excessive use will result in predictable thrombocytopenia and increase the likelihood of side effects. The median maintenance dose in patients with ET is 2 mg/day administered in divided doses. Data on more than 3000 patients with a variety of MPNs complicated by extreme thrombocytosis are available. In addition, follow-up of more than 500 patients for more than 5 years had been reported. Anagrelide has been shown to be an effective drug in the treatment of ET, resulting in a median time to response of 2.5 to 4 weeks. An effect on platelet numbers is usually noted in 6 to 10 days. Anagrelide leads to a reduction in hematocrit in 36% of patients, but it has no effect on white blood cell numbers, systemic symptoms, or the degree of splenomegaly. In a long-term study of 35 young patients (17-48 years) followed for a median of 10.8 years (range, 7-15.5 years), more than 3-g/dL decreases in hemoglobin level were reported in eight cases (24%). Most important, the reduction in platelet numbers attributed to anagrelide use has been reported to be associated with a decrease in symptoms attributable to the thrombocythemia. Anagrelide use in 1700 patients reduced the incidence of thrombohemorrhagic episodes related to thrombocytosis associated with MPNs from 0.66 symptoms per patient before therapy to 0.07 symptoms per patient after 28 to 30 months of therapy.

The most common side effects of anagrelide resulted from its vasodilatory and positive inotropic actions. These effects resulted in complaints of headache, dizziness, fluid retention, palpitations, and high-output cardiac failure. The vasodilatory effect leads to reduced renal blood flow, resulting in fluid retention. In addition, gastrointestinal complications, such as nausea, abdominal pain, and diarrhea, are prominent. These side effects usually develop within 2 weeks of initiation of therapy and frequently diminish in severity or resolve within 2 weeks of continued therapy. Because of its ability to promote fluid retention and the development of tachyarrhythmias, anagrelide therapy should be used with caution in patients with cardiac disease and should be administered carefully to elderly patients. If congestive heart failure or arrhythmias other than tachycardia develop, anagrelide therapy should be discontinued. Prolonged anagrelide therapy may be associated with a potentially irreversible drug-induced cardiomyopathy that is reminiscent of tachycardia-induced cardiomyopathy. Dose reduction can be used to lessen the degree of tachycardia or fluid retention. Before the institution of anagrelide, it is recommended that a basic cardiac evaluation be performed, including an assessment of cardiac risk factors, a careful cardiac history, and an electrocardiogram, which can be used as a baseline if the patient develops rhythm disturbances. Patients should avoid caffeine if feasible because it might trigger palpitations. Acetaminophen may be useful for treatment of the headaches. The carrier for the anagrelide is lactose, and patients who develop nausea, diarrhea, and abdominal pain with anagrelide therapy are frequently lactase deficient, and the use of LactAid results in resolution of such symptoms. Although most adverse effects are mild or moderate, in one series, therapy was discontinued in 16% of patients because of intolerable side effects, especially headache, nausea, fluid retention, and, rarely, frank congestive heart failure. Anagrelide has no mutagenic activity, but its use is not currently advised during pregnancy. Because of its small molecular weight, it is believed to be capable of crossing the placenta and thus may lead to fetal thrombocytopenia. Anagrelide does not appear to be leukemogenic. Anagrelide therefore appears to be a suitable drug for the treatment of young, symptomatic patients with ET and for those who are resistant or refractory to front-line treatment with hydroxyurea.

The approval of anagrelide for ET patients was based on the completion of phase 2 trials, and its superiority to the standard of care was never validated by the performance of a randomized phase 3 trial until recently. Hydroxyurea and anagrelide have now been compared head to head in a large randomized trial of 809 high-risk patients with ET, all treated also with low-dose aspirin (75 mg/day).[27] Overall, patients randomized to anagrelide (and aspirin) were more likely to reach the composite primary end point of major thrombosis (arterial or venous), major hemorrhage, or death from vascular causes (P = .03) (Fig. 68-5). When individual end points were assessed, arterial thrombosis, major hemorrhage, and the development of MF were all significantly more frequent in patients treated with anagrelide (P = .004, .008, and .01, respectively). Anagrelide and aspirin seemed to offer at least partial protection from thrombosis because the prevalence of thrombotic events (8% at 2 years) was significantly less than

<50	Interferon	Anagrelide Hydroxyurea
50–75	Hydroxyurea	Interferon Anagrelide
>75	Hydroxyurea	Anagrelide Busulfan

that observed in the control arm of a previous study (28%). Intriguingly, the number of venous thromboses was less frequent in patients treated with anagrelide (P = .006). In addition patients with *JAK2V617F*-positive ET were more sensitive to therapy with hydroxyurea but not anagrelide. Also, the incidence of discontinuation of anagrelide therapy because of drug-related adverse events was significantly greater than that observed with patients receiving hydroxyurea. Based on this large randomized study, hydroxyurea is presently considered first-line therapy for patients with high-risk ET (Table 68-7). Although equivalent control of the platelet count was achieved with both agents, hydroxyurea proved superior, perhaps because of its ability to reduce not only platelet numbers but also leukocyte numbers, which have been associated with thrombosis in ET patients. In addition, the combination of anagrelide and low-dose aspirin was associated with a higher incidence of bleeding episodes, suggesting that aspirin therapy might be best avoided in patients being treated with anagrelide.

Interferon-α has been used to treat the thrombocytosis associated with MPN with increasing frequency since the 1990s. INF-α acts by directly inhibiting megakaryocyte colony formation and secondarily by inhibiting the expression of thrombopoietic-stimulating cytokines, such as GM-CSF, G-CSF, IL-3, and IL-11 and by stimulating the production of negative regulators of megakaryocytopoiesis, such as IL-1ra (receptor agonist) and macrophage inflammatory protein 1 (MIP-1a). INF-α inhibits thrombopoiesis by suppressing thrombopoietin-induced phosphorylation of the *JAK2* substrates, MPL and STAT5. Furthermore, INF-α also induces the production of suppressor of cytokine signalling-1 (SOCS-1), which inhibits thrombopoietin-mediated cell proliferation. In a total of 212 patients treated with INF-α in a total of 11 different clinical trials, a response rate of approximately 90% was reported. Therapy was administered to outpatients, most frequently at an initial dose of 3 million units daily, and usually produced a rapid decrease in platelets within 2 months. The mean time to complete response with a daily dose of 3 million units daily was about 3 months. INF-α was effective in patients who had received other chemotherapeutic agents and in patients resistant to conventional cytotoxic drugs. In the majority of patients, the INF dose required to maintain a normal platelet count during maintenance therapy was lower than the induction dose. In one study, 61% of patients required 3 million units three times a week, 15% once a week, and 24% daily. In addition, sustained remissions that persisted for 3 to 36 months were achieved with INF-α therapy in 9% to 16% of patients. INF-α is reported to be nonmutagenic and to not cross the placenta, making it a useful drug for the treatment of the symptomatic pregnant patient with ET. Reduction in platelet numbers with INF results in a marked improvement in clinical symptoms. Toxicity, especially in older patients, the need for parenteral administration, and cost limit the usefulness of INF-α. Side effects include flulike symptoms during induction therapy, such as fever, bone and muscle pain, fatigue, lethargy, and depression. Symptoms are frequently controlled with acetaminophen. Long-term administration of INF-α can result in mild weight loss; alopecia; retinal abnormalities; rarely, a reversible form of sarcoidosis and a reversible form of left-sided heart failure; and the development of autoimmune conditions, including thyroiditis leading to hypothyroidism and autoimmune hemolytic anemia. Patients may develop neutralizing antibodies to recombinant INF, leading to a concomitant rise in platelet numbers. In such a situation, use of leukocyte INF-α results in an excellent response. In one review, it was reported that 25% of 273 patients failed to continue to receive INF therapy either because of poor compliance or side effects.

A semisynthetic protein polymer conjugate of INF-α 2b, pegylated INF (PEG-IFNa2b), was anticipated to be superior to unmodified INF as related to its adverse event profile and efficacy when used to treat ET patients. This formulation of INF provides prolonged activity that permits once-weekly dosing. Normalization of blood counts occurred after a median time of 2 to 3 months; 12% of patients discontinued therapy because of inability to tolerate the drug, and 17% did not achieve normalization of their platelet counts. The majority of side effects were WHO grade 1 or 2, although some encountered grade 3 toxicity, primarily fatigue and flulike symptoms. More importantly, no thromboembolic or hemorrhagic complications occurred during the period of treatment, although 12 thrombotic events occurred in 42 patients (24%) in the 24 months before the institution of therapy. This form of INF, however, appears to lead to a similar frequency and severity of side effects during long-term use as experienced with conventional INFs. Interestingly, the use of another pegylated form of INF (peg-IFNα-2a) in patients with PV was able to decrease the percentage of mutated *JAK2* allele in 24 of 27 treated patients from a mean of 49% to a mean of 27%. The use of this form of INF appeared to be associated with fewer side effects than standard forms of INF or peg-IFNa-2b. This form of pegylated IFN has been used to treat approximately 40 patients with ET with more than 75% of patients achieving a complete hematologic remission.[28] Almost 40% of patients with *JAK2V617F*-positive ET had a reduction in their *JAK2V617F* allele burden with occasional patients no longer having detectable *JAK2V617F*, leading to their being classified as having achieved a complete molecular remission. Although hematologic remissions were frequently achieved after 3 months of therapy, the effects on *JAK2V617F* were observed after 6 months of treatment. Most patients were successfully treated with 45 to 90 μg/weekly, and 22% of patients ceased therapy because of toxicity. Surprisingly, the hematologic and molecular responses persist for a number of months after discontinuation of therapy, suggesting that intermittent therapy may be an acceptable means of chronically administering this drug. No data indicating whether IFN therapy delays or prevents the evolution to MF are available. To gain a more comprehensive assessment of the clinical usefulness of INF-α, a prospective clinical trial comparing INF-α with hydroxyurea in patients with ET is underway at numerous sites in North America and Europe. Until the results of this trial are available, INF-α or anagrelide should be considered as reasonable alternatives to hydroxyurea in a patient younger than 40 years of age who has had a previous thrombotic episode (see Table 68-7), but which drug is the standard of care in so-called high-risk patients will require data emanating from the randomized trial. Although many clinicians have presumed that IFN will prove to be the superior agent, this conclusion is clearly premature and is based on small phase 2 trials. One should keep in mind that at the initiation of the randomized trial comparing hydroxyurea with anagrelide, most participants presumed that anagrelide would be the optimal therapy, which was disproven. The present randomized trial comparing IFN with hydroxyurea is therefore of utmost importance to provide the evidence for what the standard of care should be. A number of small molecule inhibitors of *JAK2* have been evaluated for the treatment of ET patients. These agents reproducibly lower platelet counts, but the definition of the appropriate role of such agents in the treatment of ET patients will require their careful evaluation in well-controlled clinical trials.

The use of platelet antiaggregating agents remains an important area of investigation. Patients with ET have an increased predisposition to hemorrhage, which is likely potentiated by the use of drugs that affect platelet function. Transient ischemic attacks and erythromelalgia associated with ET respond rapidly to aspirin alone. In erythromelalgia, symptoms disappear for 2 to 4 days after administration of a single dose of aspirin. Although these agents surely have a role in the treatment of these specific complications, their use should

be pursued with extreme caution because of the increased risk of hemorrhage. Kessler et al have determined that 32% of bleeding episodes in patients with extreme thrombocytosis and MPN occurred concurrently with the use of antiinflammatory agents.

Low-dose aspirin therapy has been uniformly recommended for virtually all patients with ET independent of their risk of developing a thrombotic event.[29] These recommendations are somewhat surprising because they are based on 2 clinical trials of the effects of low-dose aspirin therapy in PV patients, and such a trial with aspirin has never been performed with a population of ET patients. Furthermore, an independent analysis of the data from these two trials by the Cochrane Collaboration indicated that the use of low-dose aspirin therapy was associated with a statistically nonsignificant reduction in the risk of fatal thrombotic events and was not associated with an increased risk of bleeding episodes. Furthermore, after a retrospective study of 198 patients with low-risk ET, Alvarez-Larrán et al[30] concluded that antiplatelet therapy did not reduce the incidence of thrombotic events and might increase the bleeding risk if platelet counts are greater than 1000×10^9/L or aspirin is used in patients with a bleeding history (Table 68-8). Aspirin should be used with caution in patients with peptic ulcer disease. Such patients who require aspirin benefit from the concurrent use of a proton pump inhibitor such as omeprazole rather than switching them to clopidogrel. This more critical evaluation of the evidence supporting the indiscriminate use of aspirin therapy in ET patients requires serious reconsideration of this practice. In patients who absolutely require aspirin therapy, one should avoid the simultaneous administration of aspirin with a nonsteroidal antiinflammatory drug (NSAID) such as ibuprofen or naproxen because such NSAIDs are known to compete with aspirin for a common binding site on COX-1 that prevents aspirin from gaining access to and acetylating its target serine. This antagonism can be overcome by separating the time of administration of these two agents. The judicious use of aspirin in patients with a history of a thrombotic episode seems reasonable, but low-dose aspirin therapy must be restricted to patients with platelet counts of less than 1500×10^9/L and not be used in patients receiving anagrelide therapy unless they have experienced an arterial thrombotic event. The diagnosis of acquired von Willebrand syndrome should be excluded before aspirin use and considered a contraindication to the use of aspirin. Whether all patients with low-risk ET should be uniformly treated with aspirin remains speculative because prospective randomized clinical trials including appropriate numbers of patients so as to assure the resolution of this dilemma have not been completed to date.

A continuing clinical controversy revolves around the question of whether any treatment is indicated in patients with ET in whom the platelet count elevation is initially detected fortuitously and who remain largely asymptomatic. Such a decision is particularly important because the use of most chemotherapeutic agents is associated with an increased risk of the development of leukemia, and the use of platelet antiaggregating agents is not without risk. The need for such treatment can be questioned because in several studies, a relationship between the frequency of thrombotic episodes and degree of platelet elevation has not been established. One should not lapse into a false sense of security in deferring therapy, however, because the course of ET can include infrequent but dangerous thromboembolic complications, and patients may function normally for long periods of time without experiencing a life-threatening event. In a retrospective study of 99 consecutive low-risk ET patients (age younger than 60 years) who presented with extreme thrombocytosis (platelet count >1000×10^9/L) but without a previous history of thrombohemorrhagic complications, the incidence of major thrombosis and hemorrhagic events was shown to be similar during follow-up to those who were treated with prophylactic cytoreductive therapy and those who did not receive such therapy. If the clinician feels compelled to use some therapeutic intervention in young, asymptomatic patients, low-dose aspirin (81 mg/day) appears to be effective in the treatment of microvascular complications, and its use is associated with limited toxicity. Still, it seems reasonable to withhold therapy in younger, asymptomatic patients until the development of a clinically significant thrombotic or hemorrhagic event. Patients older than 60 years of age with other significant risk factors for cardiovascular complications are probably best served by immediate institution of therapy.

The management of pregnant patients with ET remains problematic.[18] The major goal of any therapeutic intervention in pregnant patients with ET should be the prevention of the vasoocclusive events that lead to placental infarction; intrauterine fetal growth retardation; and, in some cases, fetal death. Patients with *JAK2V617F*-positive ET are at a higher risk of developing such complications. In one large series, there was no significant relationship between the fetal outcome and the degree of maternal thrombocytosis or the presence of disease complications. In this series, there were no instances of excessive bleeding or other related complications during delivery. This group did not recommend the use of therapeutic platelet pheresis and, in fact, claimed that specific therapy (aspirin, heparin, or platelet pheresis) did not alter the clinical course. However, of the many patients reported in the literature who did not receive any therapy, a significant number experienced either spontaneous abortion or intrauterine deaths. Low-dose aspirin (81 mg/day), because of its profound effect on events involving the microcirculation, such as erythromelalgia and transient ischemic events, has been used with increasing frequency in pregnant patients during the first and second trimesters. Low-dose aspirin therapy is safe in pregnant women. It is recommended that aspirin be discontinued at least 1 week before delivery to avoid bleeding complications such as an epidural hematoma during delivery or during the postpartum period. Because of the high risk of bleeding in patients with platelet counts greater than 1000×10^9/L with acquired von Willebrand syndrome, aspirin therapy is contraindicated. There is limited experience reported in the literature with aspirin therapy alone, and although the results are promising, the sample size is too small to confirm a beneficial effect. The observed true birth rate, however, was 75% in those receiving aspirin compared with 43% in the group in the literature who received no therapy. Aspirin therapy has, however, recently been found to be ineffective in preventing complications in *JAK2V617F*-positive pregnant ET patients. Chemotherapeutic drugs should be avoided during the period of conception and especially during the first trimester. Both

Table 68-8 Outcome in Patients With Low-Risk Essential Thrombocythemia Followed With Careful Observation or Treated With Antiplatelet Therapy

	Observation (848 Person-Years)		Antiplatelet therapy (802 Person-Years)		
	Events *(n)*	Incidence Rate (95% CI)	Events *(n)*	Incidence Rate (95% CI)	*P*

Arterial thrombosis	8	9.4 (4.7–18.9)	13	16.2 (9.4–27.9)	.2
Venous thrombosis	7	8.2 (3.9–17.3)	4	4.9 (1.9–13.3)	.4
Bleeding	5	6.0 (2.5–14.5)	10	12.6 (6.8–23.4)	.09

From Alvarez-Larrán A, Cervantes F, Pereira A, et al: Observation versus antiplatelet therapy as primary prophylaxis for thrombosis in low-risk essential thrombocythemia. *Blood* 116:1205, 2010.

hydroxyurea and busulfan are known teratogens in animal models. In addition, busulfan and hydroxyurea reduce fertility in men. Because the greatest risk of thrombosis is postpartum, thrombosis prophylaxis should be initiated in the form of low-molecular-weight heparin and low-dose aspirin after delivery unless the patient is hemorrhaging. These measures should be continued for 6 weeks. Mothers receiving INF, anagrelide, or hydroxyurea should refrain from breastfeeding.

With the availability of INF to treat ET, it is difficult to justify the use of chemotherapeutic agents during the time of conception or during the first two trimesters of gestation. INF-α therapy is not known to be leukemogenic or teratogenic, and because it does not cross the placenta, its use may be considered during pregnancy. The manufacturers of INF-α still advise that INF-α not be used during pregnancy because adverse effects on the fetus cannot be ruled out. The effect of INF-α on male fertility remains uncertain. Anagrelide therapy should be avoided in pregnant patients because of its potential to lead to fetal thrombocytopenia.

Because none of the strategies described earlier has been tested in large clinical trials, one must develop a therapeutic strategy for an individual pregnant patient. In a patient who lacks a history of spontaneous abortions and who is totally asymptomatic but is found to be pregnant, no therapy is presently indicated, although low-dose aspirin therapy (81 mg/day) can be initiated without appreciable risk and can be continued throughout the pregnancy. Its use should be discontinued 1 week before delivery. Aspirin therapy is contraindicated in patients with platelet counts greater than 1500×10^9/L and patients with acquired von Willebrand syndrome. If a patient has experienced a thrombohemorrhagic episode or if the platelet count is rising to levels above 1500×10^9/L, therapy with a platelet-reducing agent is indicated. Platelet pheresis therapy can be attempted in selected patients, but if incomplete control is obtained, INF-α therapy is, at this point, the best option. Several successful pregnancies have been observed in patients receiving INF-α therapy. Patients with a history of a previous spontaneous abortion appear to be at a particularly high risk of developing subsequent spontaneous abortions if left untreated. At the minimum, low-dose aspirin therapy in this patient population is a reasonable therapeutic approach.

Hormone replacement therapy including oral contraceptives and estrogen replacement hormone therapy remains controversial in patients with ET. Each of these agents in the normal population is associated with an increased incidence of arterial and venous thrombosis. Intuitively, it would seem wise to avoid such agents in patients with ET who are already at an increased risk of developing thrombosis. Gangat et al retrospectively reviewed the consequences of such hormonal interventions in 305 women. Oral contraceptive therapy was associated with a high incidence of venous thrombosis occurring within the abdominal cavity, but estrogen replacement hormone therapy in menopausal women did not appear to be associated with an increased incidence of thrombosis. This observation is surprising and might be a consequence of the limited numbers of patients included within this study.

If a patient with ET develops a thrombotic episode, anticoagulation with low-molecular-weight heparin and then transition to an oral anticoagulant is recommended. The thrombotic episode places a patient into a high-risk group in which myelosuppressive therapy is clearly indicated. Whether patients should have lifelong anticoagulation or should receive only 6 to 12 months of anticoagulation after they are in a complete hematologic remission has not been investigated in a systematic fashion. Because the data necessary to make this decision are not available, this decision can only be made at the discretion of the treating physician. In one small series of patients with an MPN and Budd-Chiari syndrome from a single center, long-term anticoagulation was successfully avoided by treating these patients without oral anticoagulants but with chronic hydroxyurea and aspirin therapy. Whether such an approach is really optimal requires a more systematic randomized clinical trial. Antiplatelet therapy has been shown to reduce the risks of deep venous thrombosis and of pulmonary embolism in a variety of high-risk groups. In patients who have a new thrombosis while they are in complete hematologic remission and are optimally anticoagulated, some consideration should be given to adding low-dose aspirin if the risk of hemorrhage is not excessive.

FUTURE DIRECTIONS

Essential thrombocythemia is a hematologic malignancy with its own distinct clinical manifestations and associated complications. Better means of identifying patients at risk for developing fatal thrombotic or hemorrhagic complications are necessary to provide the basis with which to develop the optimal care of such patients. The ability to reduce the incidence of thrombohemorrhagic episodes with cytoreductive therapy in high-risk patients is well established.

Multi-institutional studies comparing the efficacy of such promising agents as INF-α or pegylated INF for the treatment of high-risk patients compared with hydroxyurea are currently being pursued. The use of low-dose aspirin therapy to reduce the number of episodes of erythromelalgia and transient ischemic attacks is widely practiced, but whether aspirin therapy should be indiscriminately used remains a subject of dispute that will only be resolved with the completion of appropriately powered clinical trials. Another pressing question that requires resolution is the degree of reduction of platelet or leukocyte numbers required for optimal management of ET patients.

Finally, the discovery of the *JAK2V617F* and MPL mutations have already had a major impact on disease classification during routine clinical practice. Diagnostic strategies have now incorporated screening for the *JAK2* and MPL mutations, although their prognostic significance remains to be clearly established. This new understanding of the molecular pathogenesis of MPN has led to the development of novel targeted therapies. The use of specific *JAK2* inhibitors for ET patients should be carefully studied in well-controlled clinical trials in which significant end points such as incidence of thrombosis, hemorrhage, and transformation to MF and acute leukemia are incorporated as end points. This is critical because the degree of reduction of platelet numbers has not served as a suitable biomarker for the development of these complications. The treatment of ET presently depends on the opinions of a small group of experts who develop treatment paradigms without the execution of randomized trials that are required for decisions to be made based on evidence. If this field is to progress, greater efforts toward the completion of well-powered clinical trials will be clearly necessary (see box on Personal Approach to Therapy of Essential Thrombocythemia).

Personal Approach to Therapy of Essential Thrombocythemia

The optimal therapy for patients with ET remains uncertain. Therapy is geared toward interventions to reduce the potential for developing thrombotic episodes. Patients with the greatest risk of developing a thrombus have a number of characteristics, including age 60 years or older, history of a thrombotic event, leukocytosis (WBC ≥11,000 $\times 10^9$/L), and cardiovascular risk factors (hypertension, hypercholesterolemia, diabetes mellitus, obesity). Patients with ET or prefibrotic form of MF can frequently present with elevated platelet counts and are treated in a similar fashion by us. No known therapy is available that is capable of reversing the BM fibrosis in such patients or delaying or eliminating evolution to MF. Certain concepts, however, apply to all patients. All patients with ET should stop smoking to minimize the risk factors associated with atherosclerotic disease. Indiscriminant use of high doses of NSAIDs should be avoided because this

Personal Approach to Therapy of Essential Thrombocythemia—cont'd

practice can lead to an increased risk of hemorrhage. Use of such agents is particularly frequent in elderly patients in whom ET is common. In patients with a life-threatening thrombotic or hemorrhagic episode, plateletpheresis should be initiated in addition to starting them on hydroxyurea therapy.

In high-risk patients, cytoreductive therapy has been shown to lessen the chance of developing additional thrombotic events with the reduction of extreme thrombocytosis to platelet counts below $600{,}000 \times 10^9$/L. High-risk patients include patients older than 60 years of age and patients with a history of a previous thrombotic episode, including erythromelalgia, transient ischemic attacks, or large vessel thrombosis. Even though this treatment philosophy has been considered common practice, the recommendation to treat patients older that the age of 60 years who have not experienced a thrombotic episode with cytoreductive therapy is not based on robust data from multiple randomized trials. Asymptomatic high-risk patients without cardiovascular risk factors may not necessarily benefit from this treatment, and the decision on how to treat them should be based on individual assessment.

At present, no therapy is indicated in asymptomatic patients younger than 60 years of age. If a patient has a platelet count greater than or equal to 1500×10^9/L and acquired von Willebrand syndrome with bleeding symptoms, platelet reduction therapy is indicated to avoid the high risk of hemorrhage. In totally asymptomatic patients with platelet counts greater than 1500×10^9/L, we frequently observe the patients and do not feel compelled to treat them. Patients with acquired von Willebrand syndrome should clearly avoid the use of aspirin.

In patients requiring platelet reduction therapy, the choice among the use of anagrelide, INF-α, pegylated INF, or hydroxyurea therapy is based on patient age, ease of administration, and drug-related toxicity. Randomized trials comparing these treatments in high-risk patients are ongoing. Until the results are available, we use the following strategy. In patients older than 50 years, hydroxyurea therapy is the treatment of choice, but in younger patients, we prefer to initiate therapy with INF-α. INF therapy should be avoided in patients with a history of depression, autoimmune disorders, or retinitis. If the patient cannot tolerate INF-α or it is not available, we feel comfortable treating symptomatic patients younger than 50 years of age with anagrelide or hydroxyurea. Although we remain concerned about the leukemogenic potential of hydroxyurea, the risk appears to be low if not associated with the prior use of an alkylating agent. The development of malleolar ulcers is a frequent complication of hydroxyurea treatment and is a signal for the elimination of hydroxyurea as a therapeutic agent for that particular patient.

Patients who initially receive hydroxyurea and no longer respond to this agent or experience toxicity and require another agent should not receive an alkylating agent. This sequence of administration is associated with an extremely high risk of leukemic transformation. Patients who have had a trial of hydroxyurea and require further treatment should receive either anagrelide, INF-α, or pegylated INF. Doses of each of these agents required for disease control will, of course, be dependent on the target platelet level that one hopes to achieve. Strict control to a platelet count of lower than 600×10^9/L does not appear to be necessary. In these patients, the addition of low-dose aspirin (81 mg/day) should be considered; it is less clear to us if patients who achieve better platelet control with cytoreductive therapy should also be so treated. However, in studies from Europe addressing this question in PV, the approach of combining aspirin with cytoreduction therapy appears to minimize thrombotic complications. The use of anagrelide and aspirin in combination should be avoided because of the high risk of a hemorrhage. In patients with thrombotic episodes, especially episodes involving the microcirculation or large vessels, we administer low-dose aspirin (81 mg/day). This dose of aspirin does increase the number of bleeding episodes to a modest degree but is effective in the treatment of thrombotic events. This low-dose aspirin therapy is given in addition to an agent, which reduces platelet numbers.

Hydroxyurea can be started at a dose of 1 g/day and then adjusted to achieve the target platelet count ($\leq 600 \times 10^9$/L) without developing leukopenia. Anagrelide is initiated at 0.5 mg twice daily and increased by 0.5 mg/day every 5 to 7 days if platelet counts do not begin to drop. The usual dose to achieve platelet number control is 2.0 to 2.5 mg/day. Alternatively, combination therapy with anagrelide and hydroxyurea may be considered. Some patients do not tolerate either hydroxyurea or anagrelide. In this patient group, INF-α therapy is initiated at 3 million units three times per week subcutaneously or consideration to therapy with a pegylated form of interferon (peg-IFNα-2a) should be given. Another choice is busulfan at 4 mg/day for 2-week courses every time the platelet count rises above the normal range. Busulfan therapy is reserved for patients older than 70 years.

Complications even in young, otherwise healthy patients with platelet counts greater than 2000×10^9/L are unusual. However, these marked elevations of platelet numbers can be anxiety-provoking situations for the patient and the clinician.

In certain situations, in young, low-risk patients, treatment should be instituted. Surgery can increase the risk of thrombosis, and the use of antiinflammatory agents can increase the risk of bleeding postoperatively. Under these circumstances, the platelet count should be lowered to the normal range. In pregnant patients with ET, low-dose aspirin therapy is the first treatment option. If the patient develops symptoms as a result of thrombosis, platelet reduction therapy is necessary, and INF-α therapy is the treatment of choice.

In a patient with ET and a serious acute hemorrhagic event, the site of bleeding should be determined immediately, and any antiplatelet aggregating agents should be stopped. Although the platelet count may be high, these platelets should be considered to be qualitatively abnormal, leading to defective hemostasis. The patient may have acquired von Willebrand syndrome. In patients with acquired von Willebrand syndrome, DDAVP (desmopressin) or factor VIII concentrates containing von Willebrand factor can be used immediately at the same time chemotherapy is being administered. If acquired von Willebrand syndrome is not present, the transfusion of normal platelets is suggested. In patients with persistent hemorrhage, immediate reduction of the platelet count can be achieved by platelet pheresis. If this approach fails, some consideration to the use of activated factor VIIa should be given. Hydroxyurea at 2 to 4 g/day for 3 to 5 days should be administered immediately and then reduced to 1 g/day. All patients receiving hydroxyurea should be monitored for the onset of granulocytopenia or thrombocytopenia. Reduction of platelet counts is usually observed within 3 to 5 days of hydroxyurea treatment.

In contrast, patients with acute arterial thrombosis require immediate institution of platelet antiaggregating agents. Aspirin at a dose of 81 mg/day is suggested. Patients with erythromelalgia or transient ischemic attacks will have a rapid cessation of symptoms after the use of low-dose aspirin. In a patient with a life-threatening arterial thrombosis, the platelet count should be lowered with either a combination of apheresis and hydroxyurea or with hydroxyurea alone, depending on the severity of the event. If the arterial thrombosis involves the microcirculation and is not life threatening (transient ischemic attacks or erythromelalgia), immediate low-dose aspirin therapy is indicated, and platelet reduction therapy (hydroxyurea, anagrelide, or INF-α) can be initiated using a standard dose and schedule.

CHAPTER 69

PRIMARY MYELOFIBROSIS

John Mascarenhas, Vesna Najfeld, Marina Kremyanskaya, and Ronald Hoffman

Primary myelofibrosis (PMF) is a chronic, malignant hematologic disorder characterized by splenomegaly, leukoerythroblastosis, teardrop poikilocytosis (i.e., dacryocytes), some degree of bone marrow (BM) fibrosis, increased BM microvessel density, and extramedullary hematopoiesis (EMH). In PMF, there is a profound hyperplasia of morphologically abnormal megakaryocytes and clonal populations of monocytes that may be responsible for the BM fibrosis due to the local release of fibrogenic growth factors. This disorder was first described in 1879 by Heuck. Fibrosis of the BM is not unique to PMF and may accompany many other disorders (Table 69-1). The designation PMF rather than idiopathic myelofibrosis was chosen by an international group of hematologists and hematopathologists to reflect our greater understanding of the origins of this disorder. Furthermore, this same group created the terms post–polycythemia vera (PV) myelofibrosis (post-PV MF) and post–essential thrombocythemia (ET) myelofibrosis (post-ET MF) to identify MF that is preceded by a history of PV or ET. In PMF, the BM fibrosis is believed to occur in response to the progeny of a clonal proliferation of hematopoietic stem cells (HSCs). This syndrome frequently leads to progressive BM failure. In 1951, Dameshek included PMF among the myeloproliferative disorders (MPDs). This hypothesis was largely based on clinical observations of patients with PV, chronic myeloid leukemia (CML), and ET who developed BM fibrosis and a clinical picture resembling PMF. Dameshek also noticed that each of these myeloproliferative neoplasms (MPNs) frequently terminates in a leukemic phase. In 2008, the World Health Organization (WHO) modified the terminology of myeloproliferative disorders to MPNs to correctly reflect the malignant nature of these related hematologic cancers.[1]

EPIDEMIOLOGY

Few epidemiologic studies are available to estimate the incidence of PMF. Because the chronic MPNs have not been considered in the past to be malignancies, case registries have limited data on the incidence of such chronic MPN as PMF. Review of previously published reports indicated an annual incidence rate in European, Australian, and North American localities ranging from 0.5 to 1.3 cases per 100,000 persons. The annual incidence rate of PMF in Olmstead County, Minnesota, was determined to be 1.33 cases per 100,000 persons, and in southeast England, the annual incidence has recently been reported to be 0.37 per 100,000 persons. In Japan, PMF is considered a rare disorder. The incidence of MF among survivors who were 10,000 m or less from the hypocenter of the atomic bomb explosion at Hiroshima, however, was 18 times the incidence reported from the remainder of Japan. These patients became symptomatic an average of 6 years after the bomb blast. Such data indicate a strong link between excessive radiation exposure and development of PMF, which is further substantiated by the high incidence of MF in patients who have received the contrast material Thorotrast (which contains 232Th, a radioactive element with a half-life of 1.41 × 1010 years). Thorotrast is taken up and retained indefinitely by cells of the reticuloendothelial system, which results in continuous irradiation of the liver, spleen, lymph nodes, and BM. Chronic exposure to several industrial solvents, including benzene and toluene, has also been associated with development of PMF. Unlike PV, where clusters of patients have been identified in Eastern Pennsylvania, raising the concern for possible environmental effects of waste-coal and Superfund sites, there are no definitive epidemiologic studies supporting environmental exposures in PMF. PMF has been reported as a complication of chronic benzene poisoning since the chemical was first used in the leather and shoe industries during the 1930s and 1940s. The average age at diagnosis of PMF is approximately 65 years, and most patients are diagnosed between 50 and 69 years of age. In several series, men have been affected more frequently than women, but others have failed to confirm this male predominance. Rarely, PMF has been reported in the pediatric age group. Evidence of genetic transmission exists: a higher incidence has been reported in Ashkenazi Jews than in Arabs who both live in Northern Israel.

PATHOBIOLOGY

The cellular origins of PMF were first explored in an African American female PMF patient who was heterozygous for isoenzymes of glucose-6-phosphate dehydrogenase (G6PD).These studies showed that the circulating hematopoietic cells were derived from a common HSC and that the BM fibroblasts were nonclonal in origin. Using X chromosome gene probes, the clonal origin of hematopoiesis in PMF was confirmed. The cytogenetic composition of BM fibroblasts of a PMF patient who had a clonal cytogenetic abnormality present in hematopoietic cells was shown to be absent in the BM fibroblasts, indicating that the fibroblasts were not involved by the malignant process. The development of extensive fibrosis of the BM in PMF is frequently preceded by a hypercellular phase of variable duration. The diagnosis depends on the demonstration of atypical megakaryocytes, BM hypercellularity, and minimal BM fibrosis within BM biopsies and the exclusion of other MPNs. An analysis of X-linked restriction fragment length polymorphisms of blood cells of patients at various stages of PMF demonstrated clonal hematopoiesis in advanced stages of PMF and in the prefibrotic phase. An *NRAS* mutation present in the hematopoietic cells of a PMF patient indicated that T and B cells were also involved in the malignant process in some patients, perhaps providing some explanation for the immunologic abnormalities associated with PMF. Similarly, fluorescence in situ hybridization (FISH) techniques have been used to detect clonal cytogenetic abnormalities in myeloid and in purified B- and T-cell lymphocytes in patients with PMF. These studies indicate that PMF is a clonal hematologic malignancy originating in primitive hematopoietic cells capable of producing lymphoid and myeloid cells and that the BM fibrosis represents a secondary reaction of BM stromal cells not involved by the process. If BM fibrosis is truly an epiphenomenon of the neoplastic hematopoietic cell proliferation, it may be expected to disappear if this cell population is eradicated. Reversal of MF has been observed after allogeneic stem cell transplantation (SCT) and infrequently seen after long-term administration of chemotherapy or interferon (INF). Such findings indicate that the BM fibrosis in PMF is not irreversible and is clearly a secondary consequence of the neoplastic cellular proliferation.

When PMF mononuclear cells are cloned in semisolid media, erythroid and megakaryocyte colony formation occurs in the absence

Table 69-1 Conditions Associated With Myelofibrosis

NONMALIGNANT CONDITIONS
Infections: tuberculosis, histoplasmosis
Renal osteodystrophy
Vitamin D deficiency
Hypoparathyroidism
Hyperparathyroidism
Gray platelet syndrome
Systemic lupus erythematosus
Scleroderma
Radiation exposure
Osteopetrosis
Paget disease
Benzene exposure
Thorotrast exposure
Gaucher disease
Primary autoimmune myelofibrosis
MALIGNANT DISORDERS
Primary myelofibrosis
Other chronic myeloproliferative disorders: polycythemia vera, chronic myeloid leukemia, essential thrombocythemia
Acute myelofibrosis
Acute myeloid leukemia
Acute lymphocytic leukemia
Hairy cell leukemia
Hodgkin lymphoma
Myelodysplasia with myelofibrosis
Multiple myeloma
Systemic mastocytosis
Non-Hodgkin lymphoma
Carcinomas: breast, lung, prostate, stomach

of added exogenous cytokines, a finding common to other MPNs. These findings suggest that possible genetic mutations activating several intracellular signaling pathways responsible for normal hematopoiesis might account for this autonomous in vitro hematopoiesis. In addition to a population of autonomous proliferating megakaryocyte progenitor cells, a second and more common population remains dependent on the addition of exogenous growth factors. The hypothesis that BM fibrosis in PMF is a secondary process has been explored by many groups who uniformly found that fibroblasts derived from BM explants obtained from PMF patients displayed the same physical and proliferative characteristics as normal BM fibroblasts. PMF and normal BM fibroblasts exhibited anchorage and serum dependence, contact inhibition of growth, and similar production of hematopoietic colony stimulating activities. These data suggest that BM fibroblasts and their precursor cells in PMF patients do not differ from those of normal subjects.

Many of the peripheral blood abnormalities associated with PMF may be attributed to the EMH that is characteristic of this disorder. EMH has been previously attributed to the reactivation of quiescent HSCs, which are retained at sites of prior embryonic hematopoiesis, especially in the spleen. This hypothesis has been questioned because of the observation that the spleen is not a prominent site of fetal hematopoiesis in humans and by the observation that EMH occurs in a wide variety of sites in PMF that cannot be accounted for by the fetal reversion hypothesis. $CD34^+$ cells in PMF exit from the BM; because of abnormal trafficking patterns, they are filtered out by the spleen, accumulate progressively, and continue to proliferate. Ultimately, there is an unequal distribution of $CD34^+$ cells, with a twofold greater number being present in the spleen than the BM. The EMH within the spleen is characterized by disturbances of splenic architecture, including an increased presence of megakaryocytes and their progenitor cells. Intravascular hematopoiesis within the sinusoids of the BM is a conspicuous finding in PMF. The characteristic changes of the BM vascular architecture consist of increased quantities of collagen type IV deposits associated with increased BM microvessel density, resulting in increased blood flow. The excessively dilated BM sinusoids in PMF contain prominent intraluminal foci of hematopoiesis. Evolution of the fibroosteosclerotic changes in PMF is accompanied by a striking accumulation of collagen IV and a marked luminal expansion and irregularity. The formation of a network of blood vessels has been shown to be triggered by a broad variety of tumor cells as a consequence of the production and release of angiogenic factors and is therefore not specific to PMF. This increase in BM microvessel density in PMF has been confirmed using immunohistochemical methods and has been shown to correlate with increased spleen size and to be an independent risk factor for overall survival. Vessels from patients with PMF are frequently markedly abnormal and appear as localized vascular nests consisting of numerous short vessels that are highly branched and tortuous. The increased BM microvessel density in PMF is probably mediated by megakaryocyte α-granule constituents. Transforming growth factor beta (TGF-β) and vascular endothelial growth factor (VEGF), for instance, have a profound effect on angiogenesis. The evolution of the fibroosteosclerotic process in PMF appears to be a coordinated process closely related to the vascular proliferation and also modulated by growth factors present within abnormal megakaryocytes.

Osteosclerosis is a prominent clinical feature of many patients with PMF frequently manifesting itself as bone pain. The osteosclerosis is a consequence of cytokines produced by the malignant BM cells or stroma conditioned and activated by an interaction with PMF cells. PMF-associated osteosclerosis can be reversed after allogeneic SCT with the establishment of normal hematopoiesis. Studies of both PMF patients and animal models of PMF indicate that both TGF-β and stromal cell–derived osteoprotegerin, a member of the TNF receptor family, play pivotal roles in the development of osteosclerosis. Osteoprotegerin is a decoy receptor for the receptor activator of the nuclear factor kappa-B ligand (RANKL). RANKL is a transmembrane protein expressed on the cell surface of osteoblasts that can be cleaved into a soluble form by proteases. Both soluble and membrane bound RANKL attach to RANK, a cell receptor expressed by osteoclast precursors to stimulate osteoclastogenesis. RANKL and osteoprotegerin are positive and negative regulators of osteoclast differentiation, respectively. Osteoprotegerin can reduce the production of osteoclasts by inhibiting the differentiation of osteoclast progenitor cells into mature osteoclasts, leading to the development of osteosclerosis. TGF-β is also a negative regulator of osteoclastogenesis through direct stimulation of transcriptional secretion of osteoprotegerin and downregulation of RANKL. In patients with PMF, it remains unknown if the degree of osteosclerosis is corrected with increased levels of osteoprotegerin.

A number of angiogenic growth factors, including basic fibroblast growth factor (bFGF) and VEGF, have been implicated as causative factors of the increased BM microvessel density observed in the BMs of PMF patients. Elevated serum VEGF levels have been reported in PMF, and increased expression of bFGF has been reported in PMF megakaryocytes and platelets. These angiogenic cytokines are the products of the abnormal megakaryocytes present in PMF BM, and the increased BM microvessel density observed is ultimately a consequence of a cytokine release characteristic of PMF megakaryocytes. The role of megakaryocytes in the development of fibrosis in PMF is further supported by the megakaryocytic hyperplasia with dysplastic or necrotic megakaryocytes that characterizes this disorder; by the increased circulating megakaryocytes and megakaryocyte progenitors that are present in PMF; by the association of BM fibrosis and acute megakaryocytic leukemia; and by the presence of MF in gray platelet syndrome, an inherited disorder of platelet α-granules. Ineffective megakaryocytopoiesis in PMF has been hypothesized to lead to the liberation of excessive amounts of such growth factors, leading to BM fibroblast proliferation and collagen synthesis. The platelet-derived growth factor (PDGF) content of platelets from PMF patients is decreased, indicating that a release or leakage of such growth factors by BM megakaryocytes may occur. PMF platelet PDGF and TGF-β levels have been found to be 2.0- to 3.0-fold and 1.5- to 3.0-fold higher, respectively, in PMF than in normal control participants, but

EGF levels in PMF were similar to those of control platelets. The roles of PDGF and TGF-β in the biogenesis of PMF probably are not restricted to promoting fibroblastic proliferation but are also related to the effect of these two growth factors on synthesis, secretion, and degradation of extracellular matrix components.

TGF-β enhances fibronectin and collagens types I, III, and IV as well as chondroitin or dermatan sulphate and proteoglycan gene expression. TGF-β decreases the synthesis of various collagenase-like enzymes that degrade extracellular matrices while at the same time stimulating the synthesis of protease inhibitors such as plasminogen activator inhibitor 1. The net effect of these complex interactions is the accumulation of extracellular matrix, which probably contributes to further progression of fibrosis. Additional growth factors probably are involved in the development of progressive fibrosis in PMF. Circulating megakaryocytic cells and platelets from PMF patients have been shown to possess high levels of bFGF. Because bFGF is devoid of a secretion peptide signal, bFGF is not present in media conditioned by megakaryocytic cells from PMF patients. bFGF is a potent angiogenic factor and is a mitogen for human BM stromal cells. Elevated platelet, megakaryocyte, and serum bFGF levels have been reported in PMF patients with progressive fibrosis. BFGF may be released or leaked from dysplastic and necrotic PMF megakaryocytes or platelets. These findings suggest that bFGF may also contribute to the progressive fibrosis and pronounced angiogenesis frequently observed in PMF. The mechanism by which the pathologic release of growth factors from megakaryocytes occurs in PMF remains unknown. Some have suggested that impaired megakaryocyte emperipolesis might lead to this liberation of fibrogenic cytokines. *Emperipolesis* is defined as the random entry of hematopoietic cells into the cytoplasm of megakaryocytes. This group documented increased emperipolesis of neutrophils and eosinophils in PMF and the liberation of myeloperoxidase-positive granules by the engulfed neutrophils. They correlated the degree of emperipolesis in PMF BM biopsies with the degree of BM fibrosis. They suggested the abnormal P-selectin distribution in megakaryocytes accounted for the selective sequestration of granulocytes by PMF megakaryocytes.[2]

In a number of reports, elevated thrombopoietin levels have been reported in patients with PMF. This unanticipated elevation of plasma thrombopoietin levels was not caused by enhanced production of thrombopoietin mRNA by BM fibroblasts or BM cells but was probably caused by the reduced expression of the thrombopoietin receptor by the platelets and megakaryocytes of PMF patients, leading to decreased clearance of thrombopoietin. Activated Janus kinase 2 (JAK2) has been shown to strongly promote cell surface localization and enhance protein levels of myeloproliferative leukemia virus (MPL). This effect has been shown to be caused by stabilization of the mature endoglycosidase H-resistant form of the receptor. In ET and PMF, platelets and megakaryocytes are characterized by lower MPL protein levels and most of receptors are immature Endo-H sensitive. These data suggest that a defect in JAK2 or an associated protein may be involved in the reduction of the mature MPL observed in MPN patients.

Vannucchi and colleagues studied mutant mice with reduced expression of the transcription factor GATA1 to further define the role of megakaryocytes and the development of BM fibrosis. These mice frequently develop anemia and die during gestation or after birth. The few animals that survive to adulthood recover from the anemia but remain thrombocytopenic throughout life because of a block in megakaryocyte maturation into proplatelets that results in megakaryocyte hyperplasia in the BM and the spleen and increased production of TGF-β. These animals develop a clinical picture after 15 months that closely resembles that of PMF, including anemia, teardrop red blood cells (RBCs), fibrosis of the BM and spleen, EMH in the liver, and progenitor cell mobilization into the peripheral blood. Unlike PMF in humans, the MF in the GATA1-low mice is not the consequence of a clonal disorder and does not progress to acute leukemia. Mutations in the GATA1 functional pathway in human PMF have not been described. However, at the protein level, a large number of the megakaryocytes in the BM of PMF patients are GATA1 negative, suggesting that whatever the genetic defect leading to PMF is, it involves the pathway that affects the posttranscriptional or posttranslational regulation of GATA1 in megakaryocytes. Given the central role played by GATA1 in megakaryopoiesis, it is not surprising that megakaryocytes with low GATA1 content are characterized by common morphologic abnormalities. These abnormalities include a lack of proper organization of the α-granules; abnormal P-selectin localization on the demarcation membrane system; increased emperipolesis of neutrophils through the demarcation membrane system; and increased levels of para-apoptosis, a TUNEL-negative process of cell death mediated by neutrophils and macrophages. It is conceivable that at least some of these megakaryocytes alterations may play a central role in the pathobiology of PMF. In addition, Garimella and coworkers have provided evidence that the osteosclerosis observed in GATA1-low mice is caused by the elaboration of bone morphogenetic proteins by megakaryocytes. Bone morphogenetic proteins cause abnormal stimulation of BM osteoprogenitor cells, resulting in overgrowth of cancellous bone and osteosclerosis.

Megakaryocytes are not the only cells capable of releasing cytokines that promote BM fibrosis. Levels of macrophage colony stimulating factor, a cytokine that regulates macrophage development and proliferation, are elevated in the serum of PMF patients. Monocytes and macrophages from patients with PMF can produce greater quantities of TGF-β and interleukin-1 (IL-1) than those from normal control participants. IL-1 and TGF-β are fibroblast mitogens that induce extracellular matrix protein production. Monocyte adhesion to extracellular matrix proteins has been shown to lead to the overproduction of IL-1 and TGF-β by PMF monocytes. Monocyte adhesion molecule through the adhesion molecule, CD44, appears to be involved in the induction of fibrogenic cytokines by mediating the interaction between monocytes and accumulated extracellular matrix protein deposits. The proinflammatory transcriptional factor nuclear factor kappa-B (NFκB) plays a pivotal role in the elaboration of IL-1 and TGF-β in the activation of NFκB monocytes and that of PMF patients. These investigators suggest that NFκB stimulates TGF-β production by influencing intracellular IL-1 levels and may serve as another potential therapeutic target for the treatment of PMF. An alternative means by which NFκB might be activated was recently described. MicroRNA (MiRNA) 146a functions to downregulate TNF receptor associated factor 6 (TRAF6) and IL-1 receptor associated kinase-1 (IRAK1), two of the signal transducers of NFκB. MiRNA-146a therefore serves to dampen the effects of NFκB activation by terminating an inflammatory response via a negative feedback loop with deletion of miRNA 146a, resulting in NFκB activation. These investigators have shown that miRNA-146a leads to a syndrome in mice that closely resembles human PMF (BM fibrosis, splenomegaly, anemia, thrombocytopenia, EMH), which is accompanied by cells within the spleen and BM having increased transcription of NFκB regulated genes. Whether such a defect in miRNAs influencing NFκB occurs in human PMF has yet to be explored. Abnormal cytokine expression in PMF is thought to represent an inflammatory response to the disease phenotype that contributes not only to the development of BM fibrosis, osteosclerosis, and increased BM microvessel density, but also PMF associated constitutional symptoms including weight loss, anorexia, pruritus, bone pain, and night sweats. Elevated levels of IL-8 and IL-2R have been closely correlated with the presence of constitutional symptoms, the requirement for RBC transfusions, and leukocytosis as well as inferior overall survival and leukemia-free survival. These observations raise the possibility that mutational events leading to the malignant transformation of hematopoietic cells in PMF may also lead to activation of transcriptional programs that promote hematopoietic cell survival and disease progression. The elevation of a variety of cytokines may therefore not only be responsible for the numerous epiphenomenon that occur as a consequence of the presence of these malignant cells but also act on the malignant clone affecting the proliferation and differentiation in differing microenvironments characteristic of the BM and various extramedullary sites, including the spleen. Ultimately, this may increase the risk of disease progression or leukemic transformation.

In 2005, greater insight into the molecular origins of the MPN was gained after the discovery of a gain-of-function mutation of an autoinhibitory domain of the JAK family of protein tyrosine kinases, which is involved in cytokine receptor signalling.[3] The JAK2V617F mutation results from a valine to phenylalanine mutation at amino acid JAK2V617F, which leads to ongoing phosphorylation activity, which then can bind to a cytokine receptor and promote signal transducer and activator of transcription (STAT) recruitment. This mutation is the likely cause of the hypersensitivity to cytokines that characterizes hematopoietic progenitors from each of the MPN. In a mouse BM transplant model, BM cells transduced with JAK2V617F results in a clinical phenotype that closely resembles PV including erythrocytosis, EMH, and BM fibrosis. Although 90% of patients with PV are JAK2V617F positive, approximately 50% of PMF patients harbor this mutation. The JAK2V617F mutation is homozygous in 13% of patients with PMF but in 30% of patients with PV. Homozygosity has been attributed to homologous recombination. Homozygosity of JAK2V617F in PMF patients is associated with a more frequent occurrence of unfavorable cytogenetic abnormalities. There is conflicting data as to whether the clinical course of patients with JAK2V617F-positive and JAK2V617F-negative PMF differ. Additional somatic mutations have been identified in patients with PMF that likely play a role in the biogenesis of PMF. A mutation in the transmembrane domain of the thrombopoietin receptor (cMPL) has been documented in 9% of patients with JAK2V617F-negative PMF (MPLW515L or MPLW515K).[4] Pardanani and coworkers have provided data to support the coexistence of MPL515L, MPL515K, and MPL wild-type (WT) alleles in the same patient. Furthermore, 30% of PMF patients with mutations of cMPL also have the JAK2V617F mutation. By studying archival material, the burden of MPL515L, MPK515K, and JAK2V617 in PMF patients has been shown to remain constant throughout the clinical course of patients with PMF. In a murine BM transplant assay, expression of MPLW515L but not WT MPL resulted in a rapidly progressive, fully penetrable, lethal MPN (18 days) characterized by marked thrombocytosis, leukocytosis, splenomegaly, hepatomegaly, BM megakaryocytic hyperplasia, and BM fibrosis but not erythrocytosis. These data have suggested that the MPL mutation favors the development of thrombocytosis but the JAK2V617F mutation favors the development of erythrocytosis. PMF patients with MPL515L/K mutations as compared with MPL WT PMF are older, present with more severe anemia, and are more likely to require transfusional support. Although 50% of patients with PMF have clonal hematopoiesis and lack mutations of either JAK2 or cMPL, they have a similar clinical phenotype to patients with the recently identified somatic mutations. It is therefore difficult to attribute to either of these mutations as the sole cause of PMF. It appears, however, that the genetic origins of PMF represent the culmination of multiple genetic and possibly epigenetic events. Additional genetic events which might play a role in this process have been defined by the efforts of a number of laboratories. Comparative genomic hybridization has shown that gains of cytogenetic material occur in more than 50% of PMF patients and most commonly involve gains of 9p, 2q, 3p, chromosome 4, 12q, and 13q. These chromosomal sites may harbor additional genes that play a role in the origins of PMF.

Further insight into the phenotypic heterogeneity of JAK2V617F-positive and -negative MPNs has recently been provided. Immunohistochemical analyses of BM have shown that PV is characterized by increased expression of phosphorylated STAT3 and STAT5 protein, but PMF is characterized by reduced expression of STAT3 and STAT5. This expression pattern was independent of JAK2V617F status. Such observations suggest that additional or alternative molecular events occur in PMF and PV that might play a role in the development of their distinctive clinical phenotypes.

A growing list of additional mutations have been identified in PMF over the past several years, providing further insight into the complex molecular pathology of this disease.[5] Many of these mutations impact the epigenome and can coexist in PMF $CD34^+$ cells. None of the genetic or epigenetic lesions identified thus far are specific to PMF, clearly aid in prognostication, or appear to be disease-initiating events. Table 69-2 lists the molecular lesions that have been characterized in patients with PMF.

Translocation ten-eleven oncogene family member 2 (TET2) located on chromosome 4q24 has been noted in many myeloid malignancies at a frequency of approximately 15%. Acquired somatic mutations throughout the 11 exons of this gene result in compromised catalytic activity of an α-ketoglutarate dependent enzyme responsible for oxidation of 5-methylcytosine (5mC) to 5-hydroxymethylcytosine (5hmC) in DNA. Low levels of 5hmC result in a hypermethylation phenotype at CpG sites in various DNA promoter regions. TET2 mRNA has been found to be highly expressed in Lin^-, $Sca\text{-}1^+$, $c\text{-}Kit^{hi}$ multipotent progenitors cells isolated from the BM and thymus of C57BL/6 mice. This expression pattern was maintained in myeloid progenitor cells but low in mature granulocytes. Moreover, in patient samples when compared with normal control sample, low 5hmC levels correlated with a significant decrease in DNA hypermethylation supporting a role of TET2 loss of function leading to DNA hypermethylation. It is currently believed that TET2 mutations result in loss of function and lead to the accumulation of 5hmC in DNA promoting DNA hypermethylation that may inhibit cells from differentiating beyond a HSC-like state. In vitro studies reveal that TET2 deficiency restrains hematopoietic cells from normal differentiation patterns and skews in favor of the monocyte/macrophage lineage with transgenic animals with knockout of TET2 having a phenotype resembling chronic myelomonocytic leukemia. Alterations in TET2 include base substitutions, out-of-frame insertions or deletions, and splice site mutations have been shown to occur in 15% to 20% of patients and that these mutations were more common in older patients. In families with multiple family members having an MPN, all TET2 mutations were almost universally acquired, and their incidence was similar to that of patients with sporadic PMF. Clonal analysis studies in MPN patient samples failed to define a consistent temporal sequence of acquisition of TET2 mutations with respect to JAK2 mutations and can occur late in the progression of MPNs. These two genetic events appear to occur independently. The clinical correlation of TET2 mutation status in PMF patients does not appear to provide a new prognostic marker. TET2 mutations can be found in PMF patients with and without

Table 69-2 Acquired Genetic Lesions Identified in Patients With Primary Myelofibrosis

Gene	Location	Mutation	Frequency
Janus kinase 2 (JAK2)	9p24 exon 14 9p24 exon 12	JAK2V617F	65% Infrequent
Ten-eleven translocation 2 (TET2)	4q24		17%
Enhancer of zeste homolog 2 (EZH2)	7q36.1		13%
Myeloproliferative leukemia virus (MPL)	1p34 exon 10	MPLW515L/K	5%-10%
Casitas B-lineage lymphoma (CBL)	11q23.3	Exons 8 and 9	6%
Isocitrate dehydrogenase (IDH 1 and 2)	2q33.3/15q26.1		4%
Ikaros family zinc finger 1 (IKZF1)	7p12		Infrequent
Additional sex Combs-like 1 (ASXL1)	20q11.1		Infrequent

the JAK2V617F mutation and did not influence rate of thrombosis, leukemic transformation or overall survival. It was noted in multivariate analysis that the presence of TET2 mutation did correlate with anemia (hemoglobin <10 g/dL) in PMF.

Isocitrate dehydrogenase 1 and 2 *(IDH 1/2)* located on chromosome 2q33.3 and 15q26.1, respectively, encode $NADP^+$ dependent enzymes that catalyze the oxidative decarboxylation of isocitrate to α-ketoglutarate. Mutant IDH forms preferentially transform α-ketoglutarate to 2-hydroxyglutarate and appear to promote tumorigenesis by inducing hypoxia-inducible factor 1α (HIF-1α). *IDH 1/2* mutations are found at a frequency of approximately 4% in PMF and can coexist with mutations in JAK2, MPL, and TET2. The specific IDH mutant variants seen in MPNs (IDH1R132C, IDH1R132S, IDH2R140Q) all affect arginine residues. IDH 1/2 mutations do not appear to predict for survival in PMF but do have prognostic significance in multivariate analysis in blast phase disease (PMF-BP). It is not yet clear if different IDH mutation variants carry different biologic or prognostic consequences in PMF. A significant association between IDH 1/2 mutation and non-46/1 haplotype has been observed and supports a theory that PMF patients that are nullizygous for the 46/1 haplotype are more susceptible to acquiring additional molecular lesions that contribute to a poor prognosis.

Additional sex combs-like 1 *(ASXL1)* gene is located on chromosome 20q11.1 and is responsible for encoding an enhancer of the trithorax group (trxG) and polycomb group (PcG) proteins (ETP) chromatin modifier complex. The PcG proteins (repress) and trxG proteins (activate) serve to regulate gene expression of homeotic genes, such as *Hox* genes via histone methylation. ASXL mutations have been identified in various myeloid malignancies and in highest frequency in myelodysplastic syndrome (MDS) and CMML. In a study of 64 MPN cases, ASXL1 mutations were found in five MPN patients (three with PMF), all of whom were negative for the JAK2 mutation. ASXL1 mutations can be found in the MPN HSC, suggesting acquisition early in the pathogenesis of MPNs, but the clinical significance of this mutation in PMF is not yet clear.

The Casitas B-lineage lymphoma *(CBL)* proto-oncogene is located on chromosome 11q23.3 and is believed to play a role in the maintenance of the hematopoietic pluripotent stem cell pool. CBL has the capacity to downregulate and upregulate tyrosine kinase activity by either serving as an adaptor protein and recruiting downstream targets of the pathway or by activation of E3ubiquitin-protein ligase activity and the subsequent recycling of the receptor through internalization of the receptor/ligand complex or lysosomal-directed destruction. CBL mutations were first appreciated in MPNs in the setting of mutational screening of acquired uniparental disomy of chromosome 11q with a total of 27 CBL variants identified in MPNs. Within a cohort of 579 MPN patients screened, three patients with PMF were identified with CBL mutations at an overall frequency of 6%. The majority of the CBL mutations identified were located in the RING or linker domains, resulting in impaired ubiquitin ligase activity. Additionally, the oncogenic activity of selected CBL mutant variants was tested in vitro in the ability to confer growth factor independence to IL-3 dependent cell line 32D and demonstrated enhanced proliferation in transformed cells overexpressing WT FLT3.

Ikaros is a Kruppel-like zinc finger transcription factor that has pleiotrophic function important in the development of normal hematopoiesis and is encoded by the Ikaros family zinc finger 1 *(IKZF1)* gene located at 7p.12. Mutations involving IKZF1 have been identified as a molecular event leading to transformation of chronic phase MPNs to blast phase disease and appearing to occur after the acquisition of JAK2V617F. The mutational frequency in chronic phase MPN is very low at 0.2% in contrast to 21% of blast phase MPN patients and is highly associated with del7p. The effect of *IKZF1* mutation was studied in mouse primary progenitor cells with shRNA-mediated IKZF1 deficiency and is associated cytokine hypersensitivity and increased p-STAT5 expression.

Enhancer of zeste homolog 2 *(EZH2)* gene located on chromosome 7q36.1 encodes the catalytic subunit of the histone methyltransferase polycomb repressor complex 2 (PRC2), and mutations in this gene have also been described in MPN patients. PRC2 is a multiprotein enzyme complex (EZH2, SUz12, EED and YY1) responsible for the trimethylation of lysine 27 on histone H3 (H3K27me3). Additionally, PRC2 can recruit other polycomb complexes, DNMTs and HDACs to the gene site, resulting in chromatin compaction and additional repressive activity. Upregulation of *EZH2* gene expression has been documented in MPNs, most frequently in PMF patients, suggesting a potential role of tumor suppressor gene silencing as a mechanism in disease progression. In a study of 614 patients with myeloid malignancies, 42 cases were found to have a total of 49 *EZH2* mutations. Thirty PMF patients were analyzed in this cohort, and 13% were found to have an EZH2 mutation. Microarray and single-nucleotide polymorphism (SNP) analysis did not show association with copy number alterations or uniparental disomy. Because of small patient numbers and short follow-up, it was not possible to gauge the true prognostic significance of mutated EZH2 in PMF. Retrospective studies using archived MPN BM samples to assess for EZH2 mutations have also not shown to hold prognostic significance in PMF.

A number of investigators have shown that myeloid cells in PMF (RBCs, white blood cells [WBCs], and megakaryocytes and platelets) are clonal and that they harbor the JAK2V617F or MPL515L/K mutations. Furthermore B, T, and natural killer cells isolated from PMF patients in selected cases are JAK2V617F or MPL515 L/K positive. These studies indicate that JAK2V617F and MPL mutational events originate in a cell capable of generating both myeloid and lymphoid cells such as the pluripotent HSC. The ability of primitive human hematopoietic cells to engraft sublethally irradiated immunodeficient mice is the standard surrogate in vivo assay for human HSCs. PMF $CD34^+$ cells are capable of engrafting NOD/SCID (nonobese nondiabetic/severe combined immune deficient) mice and generating myeloid and B cells that are clonal, JAK2V617F positive, and carry a patient-specific marker chromosomal abnormality.[6] The differentiation program of PMF $CD34^+$ cells after transplant into NOD/SCID mice was also remarkably different from that of normal $CD34^+$ cells, producing greater numbers of $CD34^+$, $CD33^+$, and $CD41^+$ cells but fewer $CD19^+$ cells. This predisposition to produce greater numbers of megakaryocytes has been further explored by incubating PMF, PV, and $CD34^+$ cells in vitro in the presence of stem cell factor and thrombopoietin. PMF $CD34^+$ cells displayed a far greater proliferative capacity and produced greater numbers of megakaryocytes that were characterized by a resistance to undergo apoptosis in vitro caused by overexpression of the antiapoptotic factor Bcl-XL. The megakaryocyte hyperplasia in PMF, therefore, could be accounted for by two factors, an increased ability of $CD34^+$ cells to generate megakaryocytes and the accumulation of megakaryocytes caused by Bcl-xL overexpression. Although Bcl-xL overexpression has been linked to JAK2V617F, PMF megakaryocyte Bcl-xL overexpression also occurred to a similar degree in megakaryocytes generated from $CD34^+$ cells isolated from individuals with both JAK2V617F-positive and -negative disease.

Bone marrow megakaryocytes PMF have been reported to produce greater amounts of TGF-β than MKs generated in vitro from normal volunteers or patients with PV.[7] An immunophilin FK506 binding protein 51 (FKB51) is overexpressed in PMF megakaryocytes, and that FKB51 overexpression leads to activation of NFκB in PMF MKs. Cells with activated NFκB produce greater amounts of TGF-β. This effect of NFκB is likely indirect because NFκB cannot directly increase transcription of TGF-β because its promoter does not have NFκB binding sites. These studies suggest that NFκB or TGF-β inhibitors might be useful in preventing the progression of BM fibrosis in PMF.

The number of unilineage and multilineage hematopoietic progenitor cells constitutively mobilized into the blood of PMF patients is dramatically increased. The number of $CD34^+$ cells present in the peripheral blood in PMF is 360 times greater than in normal control participants and 18 to 30 times higher than in patients with PV or ET. These findings are so striking that some investigators have suggested that the quantitation of $CD34^+$ cells in the peripheral blood might serve as a means of discriminating PMF from other MPNs. A level of 15×10^6/L of $CD34^+$ cells in peripheral blood allows

differentiation of PMF from PV and ET. The numbers of circulating $CD34^+$ cells tend to increase as the disease progresses and that there is a close correlation between patients presenting with more than 300×10^6 $CD34^+$ cells/L of peripheral blood and imminent evolution to leukemia. These findings suggest that PMF $CD34^+$ cell trafficking abnormality is caused by the inability of these cells to be retained within the BM or their premature release into the peripheral blood.

Primary myelofibrosis is characterized not only by the constitutive mobilization of $CD34^+$ hematopoietic cells but also endothelial progenitor cells into the peripheral blood. Endothelial progenitor cell mobilization predominates during the prefibrotic phase of PMF while hematopoietic stem/progenitor cell mobilization occurs characteristically in more clinically advanced phases of the disease. This dysregulation of stem cell trafficking likely ultimately leads to the seeding of extramedullary sites with primitive hematopoietic and endothelial cells, which results in production of EMH within the liver and spleen as well as a variety of other organs. Several proteolytic pathways have been documented to play a role in cytokine-mediated stem cell mobilization. Proteins released by activated neutrophils cleave vascular adhesion molecule-1 (VCAM-1) expressed by stromal cells, leading to the disruption of a key adhesive interaction between VCAM-1 and very late antigen-4 (VLA-4) expressed by HSCs and progenitor cells. The interaction between stromal cell–, endothelial cell–, and osteoblast-derived stromal cell–derived factor-1 (SDF-1) and the CXC chemokine receptor-4 (CXCR-4) expressed by HSCs and progenitor cells is also believed to determine patterns of stem cell trafficking. Proteases, including neutrophil elastase, soluble matrix metalloproteinase-9 (MMP-9), and cell-bound MMP-9, have been shown to play a role in the constitutive mobilization of $CD34^+$ cells that occurs in PMF patients. The concentrations of soluble VCAM-1, a degradation product of VCAM-1, is elevated in the plasma of PMF patients, and these levels correlate with the absolute numbers of $CD34^+$ cells in the peripheral blood. In addition, these elevated levels of proteases have been shown to be responsible for degradation of the chemokine SDF-1, which plays a role in retention of $CD34^+$ cells within the BM because the degradations products lack the ability to attract $CD34^+$ cells, thereby favoring their mobilization. Furthermore, CXCR-4 expression by PMF $CD34^+$ cells is downregulated, which may account for altered SDF-1–CXCR-4 interactions participating in $CD34^+$ cell mobilization. This downregulation of CXCR4 expression can be reversed in vitro by treatment with chromatin modifying agents, suggesting that this eve2nt might be attributable to epigenetic events. Furthermore, the expression levels of CXCR4 were significantly lower in patients with a high burden of JAK2V617F (allele frequency, 75%) compared with patients with low-burden JAK2V617F, suggesting the dependence of gene expression on the frequency of the mutated allele. Similar degrees of $CD34^+$ cell mobilization are observed in post-ET and post-PV MF as occurs in PMF. In PV patients, Passamonti and coworkers have demonstrated a relationship between JAK2V617F gene dosage and the degree of constitutive mobilization of $CD34^+$ cells, suggesting that such mobilization may be a consequence of the transition from JAK2V617F heterozygosity to homozygosity that is accompanied by granulocyte activation. Drugs that target the proteases responsible for constitutive $CD34^+$ cell mobilization may present an intriguing strategy to prevent the establishment of extramedullary sites of hematopoiesis in patients with PMF.

The kinetics of engraftment of normal stem cells after allogeneic SCT in PMF patients and the slow regression of fibrosis after transplant lead one to question if the distorted BM architecture associated with fibrosis in PMF actually disrupts the functions of the BM microenvironment. In PMF patients, normal stem cells engraft after transplant and hematopoietic cell recovery occurs before the BM fibrosis has resolved. These observations raise some questions concerning the prospects for success with strategies for the treatment of patients with PMF that are directed solely toward reversing the BM fibrosis rather than eliminating the malignant clone and its progeny. Furthermore, in mouse models of MF, inhibition of TGF-β1 was capable of preventing the development of BM fibrosis but did not rescue animals from a fatal MPN.

CLINICAL MANIFESTATIONS

Table 69-3 lists the symptoms and physical findings of patients with PMF at presentation.

Approximately 25% of patients are entirely asymptomatic and come to medical attention because of an enlarged spleen detected during routine physical examination or because of an abnormal blood cell count or peripheral blood smear. The most common symptom in PMF is fatigue, which in the majority of patients affects the quality of daily life and social activities. Fatigue may be the result of anemia, which leads to the associated complaints of weakness, dyspnea on exertion, and palpitations. But when patients were questioned with the aid of specific questionnaires, fatigue was found to be a significant burden even in patients who were not anemic. The presence of anemia, splenomegaly, and other features associated with advanced disease favored the development of higher levels of fatigue. Other nonspecific constitutional symptoms, including fever, night sweats, pruritus, bone pain, and weight loss, are present at diagnosis in 20% to 50% of patients with PMF and are more frequent in older patients.

With enlargement of the spleen, various syndromes characterized by abdominal discomfort emerge. Pressure of the spleen on the stomach may lead to delayed gastric emptying and early satiety. Patients may merely complain of a dull, heavy sensation in the left upper quadrant. Pain of extreme severity, simulating an acute abdominal emergency, is produced by splenic infarction. Pressure of the spleen on the colon or small bowel may be responsible of severe, disabling diarrhea.

Thrombotic episodes may rarely be the presenting feature of the disease or may occur during its course with a probability of 9.6% at 5 years, a rate higher than in the control general population. Thrombosis may be venous (cerebral venous sinus thrombosis, splanchnic vein thrombosis, deep venous thrombosis, pulmonary thromboembolism) or arterial (stroke, transient ischemic attacks, retinal artery occlusion, myocardial infarction, angina pectoris, and peripheral arterial disease). The cellular phase of PMF with thrombocytosis and presence of cardiovascular risk factors such as hypertension, smoking, hypercholesterolemia, and diabetes are the independent predictors of thrombosis.[8] After splenectomy, the rate of thrombosis increases and is associated with the development of thrombocytosis after the procedure. A systematic review of PMF patients with the *JAK2V617F*

Table 69-3 Summary of Symptoms and Physical Findings of Patients With Primary Myelofibrosis Detected at Diagnosis

Symptom or Finding	Incidence (%)
Asymptomatic	16-30
Fatigue	47-71
Fever	5-15
Weight loss	7-39
Night sweats	6-21
Symptoms due to enlarged spleen	11-48
Bleeding	5-20
Gout or renal stones	6-13
Pallor	60
Petechiae or ecchymoses	15-20
Splenomegaly	89-99
Hepatomegaly	39-70
Peripheral edema	13
Evidence of portal hypertension	2-6
Lymphadenopathy	1-10
Jaundice	0-4

mutation failed to clearly define a statistically significant increased risk of thrombosis in this population, and further studies with larger numbers of PMF patients need to be conducted.

Bleeding problems may complicate the clinical course of PMF patients. Bleeding may be trivial, as manifested by petechiae and ecchymoses, or it may be life-threatening as a result of uncontrollable esophageal bleeding. It may result from thrombocytopenia or poor platelet function. Bleeding may be only initially encountered during a surgical procedure such as splenectomy; in this case, the bleeding diathesis may result from inapparent disseminated intravascular coagulopathy (DIC) and has the potential for catastrophic consequences.

Occurrence of isolated sites of ectopic sites of myeloid metaplasia has been reported, particularly in the pulmonary, gastrointestinal, central nervous, and genitourinary systems. EMH can rarely occur in the skin, manifesting as nontender, occasionally pruritic red, pink, or violaceous plaques, papules, or hemangioma-like nodules. These dermal infiltrates, when biopsied, are composed of combinations of myeloid, erythroid, and megakaryocytic cells. Patients with nonsplenic ectopic myeloid metaplasia present with cough and "large lung tumors," headache, or paralysis resulting from "brain tumors or spinal cord tumors," small bowel obstruction, or intractable ascites from ectopic implants of hematopoietic tissue in the gut or peritoneum. Myeloid metaplasia of the renal pelvis, ureters, and bladder and renal parenchymal infiltration have been observed. Expansion of hematopoietic tissue at the urethral meatus may be confused with a urethral carbuncle. Such strategically localized sites of EMH may lead to renal failure or obstruction of both kidneys and bladder dysfunction. Ascites occurring in a patient with PMF may result from peritoneal or mesenteric implants of extramedullary hematopoietic tissue or from portal hypertension. If the ascites result from peritoneal implants, the fluid is always exudative and sterile and frequently contains myeloid, erythroid, and megakaryocytic elements. Such cytologic studies should routinely be performed on ascitic or pleural fluid obtained from patients with PMF. Unusual sites of EMH have been reported in the gallbladder and lacrimal fossae.

Table 69-3 lists the prominent physical findings in patients with PMF.[9] Splenomegaly serves as the hallmark of the disease. Its extent may vary, but massive splenomegaly, with the organ occupying the entire left side of the abdomen and extending into the pelvis, may occur in 35% of patients. Hepatomegaly occurs in almost 70% of cases, and lymphadenopathy is observed in 10% to 20%, but the degree of nodal enlargement is frequently only moderate. Other important physical findings include pallor, peripheral edema, jaundice, and bony tenderness. Acute monoarticular inflammation caused by secondary gout is seen in 6% of patients.

Portal hypertension may occur and is a result of massive increases in hepatic blood flow and intrahepatic obstruction. Clinical features of portal hypertension, such as ascites or esophageal varices, occur in 9% to 18% of patients with PMF. Occasionally, cirrhosis or evidence of thrombosis of the portal or hepatic veins has been reported. In patients with portal hypertension, thrombotic lesions in small- or medium-sized portal veins and in extrahepatic portal veins were observed. Nodular regenerative liver hyperplasia occurred in 14.6% of cases and correlated closely with the presence of portal vein lesions. They concluded that thrombosis is the most likely cause of portal venous obliteration and portal hypertension in PMF and that clinically significant thrombosis confined to small intrahepatic veins or large hepatic veins should be considered in any patient with PMF. In this autopsy series, portal and hepatic venous disease occurred even in the absence of signs of portal hypertension. Such a finding is consistent with subclinical thrombosis with recanalization occurring fairly commonly in this patient group.

Rarely, the development of PMF can be preceded by the appearance of multiple cutaneous edematous plaques and nodules characteristic of the Sweet syndrome, a cutaneous process occurring in response to a number of hematologic malignancies. Pyoderma gangrenosum has been reported to be associated with PMF, and atypical pyoderma gangrenosum is reported to be a complication at splenectomy incision.

Primary myelofibrosis may be associated with the development of pulmonary hypertension. These patients present with progressive dyspnea, signs of biventricular heart failure, and rapidly increasing hepatosplenomegaly. An elevation in pulmonary artery pressure can be documented by transthoracic Doppler echocardiography and right heart catheterization. Many of these patients succumb to cardiopulmonary complications within 18 months of the documentation of pulmonary artery hypertension. The development of pulmonary artery hypertension can be attributed to thromboembolic disease, EMH diffusely involving the lung, or pulmonary fibrosis due to the elaboration of fibrogenic cytokines from dysfunctional circulating megakaryocytes and platelets. BM fibrosis also occurs in patients with primary pulmonary hypertension and can be associated with anemia and thrombocytopenia. These patients can be distinguished from patients with PMF by their lack of high levels of circulating $CD34^+$ cells, teardrop RBCs, hematopoietic cell clonality, and JAK2V617F negativity.

The nephrotic syndrome can occasionally be associated with PMF. Renal EMH is a constant finding in these cases, but renal biopsy may reveal also a picture of mesangioproliferative glomerulopathy or membranous glomerulonephritis. Immunocomplexes deposition with subepithelial electron dense deposits caused by immunodysfunction of PMF has been proposed as the pathogenetic explanation for this association.

Primary myelofibrosis may be associated with a preexisting or simultaneously appearing autoimmune disease, such as systemic lupus erythematosus (SLE), scleroderma, primary biliary cirrhosis, ulcerative colitis, polyarteritis nodosa, or juvenile rheumatoid arthritis. In addition, autoimmune forms of MF have been described distinct from PMF and are most commonly associated with SLE. These patients characteristically have cytopenia and BM fibrosis but have a limited degree of splenomegaly and only mild numbers of teardrop RBC and immature myeloid cells in the peripheral blood. Patients with autoimmune MF frequently have a positive direct antiglobulin test result and antinuclear antibodies (ANAs) but are JAK2V617F negative.

LABORATORY MANIFESTATIONS

Careful examination of the peripheral blood smear and BM (Fig. 69-1) permits ready diagnosis of PMF. Leukoerythroblastosis with teardrop RBCs strongly suggests this diagnosis. The leukoerythroblastic condition is characterized by the presence of nucleated RBCs and immature myeloid elements in 96% of cases. Megathrombocytes and megakaryocytic fragments are frequent findings. The number of teardrop erythrocytes (i.e., dacryocytes) decreases after splenectomy or institution of chemotherapy, which has led some to suggest that splenic fibrosis causes the development of these RBC changes. In approximately 60% of patients, hemoglobin levels drop to less than 10 g/dL. The degree of anemia is not infrequently difficult to estimate by hemoglobin or hematocrit determinations because individuals with large spleens often have expanded plasma volumes and apparent anemia, which is largely dilutional in nature. Most patients have normochromic normocytic RBC indices. The anemia may be caused by decreased production because of erythroid hypoplasia or ineffective RBC production and shortened RBC survival. The cause of the hemolytic anemia is usually multifactorial, with contributions from hypersplenism, a defect in RBCs resembling paroxysmal nocturnal hemoglobinuria, and antierythrocyte autoantibodies.

Hypochromic microcytic anemia resulting from iron deficiency secondary to blood loss may develop in 5% of PMF patients. Blood loss may be caused by leaking esophageal varices, duodenal ulceration, gastritis, or intravascular hemolysis. Occasionally, a patient with PMF may develop an occult malignancy or a site of EMH within the gastrointestinal tract, which may serve as a bleeding source. Unexplained microcytosis (mean corpuscular volume >80 fL) has been reported as a laboratory feature in PMF and in general has not been shown to have prognostic relevance. Macrocytic anemia may complicate PMF. Folic acid absorption is normal in these patients, and the folic acid deficiency probably results from increased use.

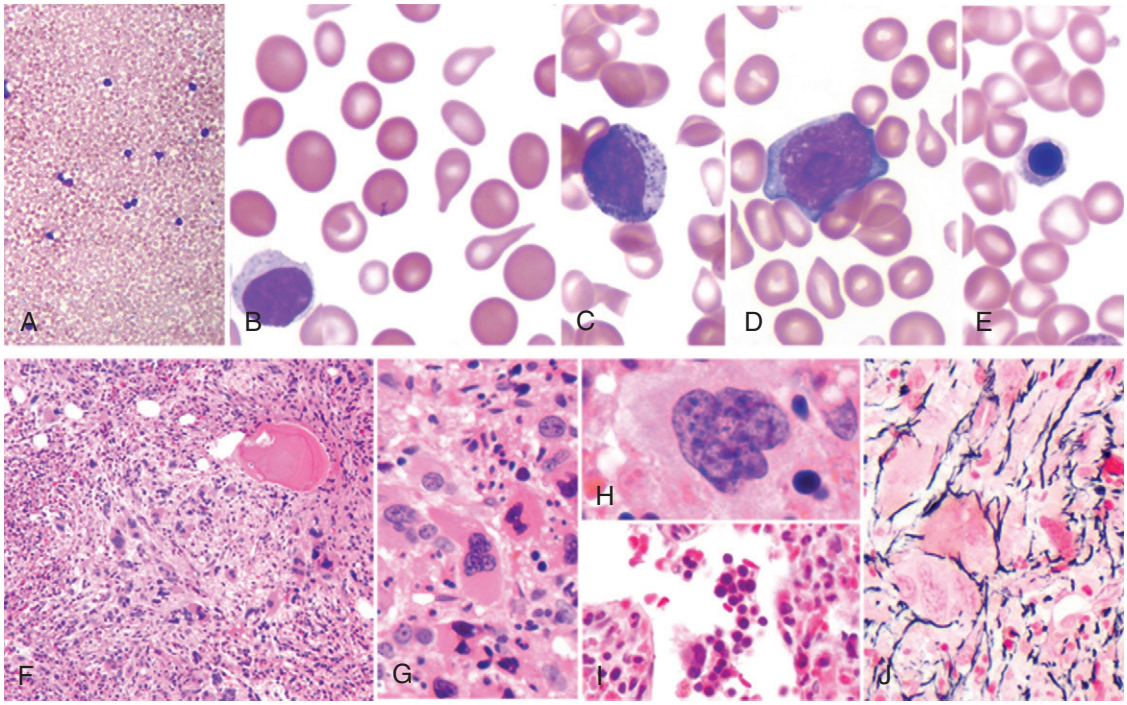

Figure 69-1 PRIMARY MYELOFIBROSIS (PMF). Peripheral blood and bone marrow (BM) biopsy. The leukocyte count can vary in PMF from leukopenia to marked leukocytosis. In the case illustrated, the count was normal **(A).** However, the smear showed numerous dacryocytes, or teardrop forms **(B),** and a leukoerythroblastic picture (**C** to **E**), that is the presence leukoblasts, or immature granulocytic precursors **(C),** including myeloblasts **(D),** and circulating nucleated red blood cells or erythroblasts **(E).** The BM biopsy is frequently hypercellular **(F)** and comprised of an atypical megakaryocytic and granulocytic proliferation **(G)** in which some of the megakaryocytes have atypical and pyknotic nuclei. Other megakaryocytes **(H)** are considered to have nuclei that are "cloudlike." The BM biopsy frequently shows sinusoidal hematopoiesis **(I)** and significant fibrosis as illustrated by a reticulin stain **(J).**

Leukopenia can occur in 13% to 25% of patients, and leukocytosis is seen in one-third. Occasional blast cells and granulocytes with the pseudo–Pelger-Huët anomaly are frequent findings. The leukocyte alkaline phosphatase score is high in more than half of patients but low in about one-third. Platelet counts of less than 100,000/mm^3 are observed in 31% of patients, and platelet counts of more than 800,000/mm^3 have been observed in 12%. In the prefibrotic phase of the disease, almost 90% of patients had platelet counts greater than 500,000/mm^3. Defective platelet aggregation is common, and platelets frequently do not respond to collagen or epinephrine. A variety of qualitative platelet anomalies have been documented by abnormal in vitro aggregation patterns. In 15% of patients, abnormalities suggestive of ongoing DIC are found, including decreased platelet numbers, decreased levels of factor V and VIII, and increased fibrin-split products. Usually, when DIC occurs in PMF, it produces no symptoms and unfortunately may only become clinically apparent after surgical intervention. Associated liver dysfunction may also be a contributory factor to prolongation of the prothrombin time.

Additional laboratory abnormalities are quite common. In one series, lactic acid levels were elevated in 95% of patients, bilirubin levels in 40%, uric acid in 60%, and alkaline phosphate and serum glutamic oxaloacetic transaminase levels in 50%. Patients with PMF have decreased levels of total cholesterol. The ratio of high-density lipoprotein cholesterol to low-density lipoprotein cholesterol is diminished.

A variety of immunologic abnormalities have been reported in PMF, including the presence of ANAs, elevated rheumatoid factor titers, direct Coombs test positivity, lupus-type circulating anticoagulants, hypocomplementemia, BM lymphoid nodules, and increased circulating immune complexes. In one series of 50 patients with PMF, increased quantities of circulating immune complexes were detected in 39% and found to be associated with increased disease activity as manifested by increased transfusion requirements, bone pain, and fever. Some investigators have suggested that abnormalities of the complement system may be important in the disease progression of PMF, and others have hypothesized that low levels of C3 may predispose these patients to develop serious bacterial infections. A remarkably high incidence of monoclonal gammopathies has been reported in PMF, with such benign gammopathies occurring in 8% to 10% of patients in some series. A number of cases of the simultaneous occurrence of a plasma cell dyscrasia and PMF have been reported.

Successful BM aspiration is unusual, accomplished in only six of 48 cases in one series, with the tap completely dry in 50% of cases. A BM biopsy is necessary in all cases for the diagnosis and monitoring of the disease. The amount of residual hematopoietic cellular tissue and the degree of BM fibrosis are the key elements that should be assessed. Some caution should be taken in using repeated BM biopsy specimens to diagnose PMF. A BM biopsy performed at the site of a previous bone injury during the healing process frequently results in confusion because of primary callus formation at that site. Most BM biopsies in PMF are hypercellular and are remarkable for increased numbers of megakaryocytes. BM fibrosis and osteosclerosis were seen in 67% and 54% of cases, respectively. The characteristic morphologic features include patchiness of the hematopoietic cellularity and the reticulin fibrosis, some microscopic fields being cellular and others depleted of hematopoietic cells. The amount of reticulin may vary from field to field. The megakaryocytes are increased in numbers and often are arranged around and within the sinuses and not always clustered in groups. They are large with irregular, roundish, cloudlike nuclei and distended BM sinusoids frequently containing intravascular hematopoiesis. The BM biopsies reveal a substantial increase in vascularity. The BM microvessels are more tortuous and branched than observed in normal control participants. The increased microvessel density is correlated with increased VEGF expression by megakaryocytes. A rare histologic variant of PMF is the so-called MF with fatty BM in which the BM is characterized by myeloid hypoplasia associated with fairly complete fatty substitution, mimicking the BM

of aplastic anemia. These patients frequently have areas of clusters of densely aggregated hematopoietic elements exhibiting the histopathologic characteristics of PMF and large numbers of hematopoietic progenitors circulating in their peripheral blood. This variant of PMF is likely caused by the abnormal trafficking of hematopoietic cells from the BM to extramedullary sites, consistent with the osteosclerosis observed in patients with PMF, increased thickness of some bone units with new lamellae and focal areas of woven bone. There is a net decrease in osteoclast number and conversion of trabecular pillars into plates.

Progressive fibrosis is frequently observed in patients who did not have maximal MF at the time of the initial biopsy. Thiele and colleagues presented data to indicate an early prefibrotic subtype of PMF with no or minimal BM reticulin and another phase with conspicuous fibrosis and osteosclerotic changes of the BM.[10] Based on a careful histomorphometric evaluation of the BM, they concluded that in a subset of patients there was a progressive fibroosteosclerotic process during the evolution of the disease that was paralleled by an increase in numbers of small megakaryocytes with irregular perimeters and megakaryocytes with naked nuclei. The clinical and morphologic findings of patients with the prefibrotic stage of PMF have been further characterized. Although a steady progression to BM fibrosis has been demonstrated in patients with the prefibrotic phase, fibrosis may remain static or diminish in the more advanced stages of PMF.

Different scoring systems for pathologically grading the BM cellularity and fibrosis have been used with the aim of staging and documenting progression of the disease. In a recent European consensus conference, the importance of age-dependent decrease in cellularity was recognized (Table 69-4). Grading of MF was simplified by using four easily reproducible categories, including differentiation between reticulin and collagen. A consensus was reached that the density of fibers must be assessed in relation to the hematopoietic tissue. This feature is especially important to avoid a false impression of a reduced fiber content in fatty or edematous BM samples after treatment. The progression of BM fibrosis in PMF is accompanied by expression of subsets of collagenases that is independent of the JAK2V617F status.

Morphologic examination of the spleen reveals foci of EMH in the sinusoids of the red pulp, where megakaryocytes, myeloid elements, and nucleated erythroid elements are seen. Follicular atrophy in the white pulp frequently occurs. The extramedullary hematopoietic cells belonging to each of the myeloid lineages can be distributed in the spleen diffusely or be limited to macronodules. The predominance of immature granulocytic forms is associated with an especially poor prognosis. Pathologic examination of the liver reveals hematopoietic cellular elements within the sinusoids. Sinusoidal dilatation is a common finding, as well as prominent intrahepatocyte and Kupffer cell hemosiderin deposition. A marked increase in the hepatic reticulin network has also been observed.

Table 69-4 Grading of Myelofibrosis According to the European Consensus Criteria

Grading	Description*
MF-0	Scattered linear reticulin with no intersections (cross-overs) corresponding to normal bone marrow
MF-1	Loose network of reticulin with many intersections, especially in perivascular areas
MF-2	Diffuse and dense increase in reticulin with extensive intersections, occasionally with focal bundles of collagen, focal osteosclerosis, or both
MF-3	Diffuse and dense increase in reticulin with extensive intersections and coarse bundles of collagen, often associated with osteosclerosis

Data from Thiele J, Kvasnicka HM, Facchetti F, et al: European consensus on grading bone marrow fibrosis and assessment of cellularity. *Haematologica* 90:1128, 2005.
*The quality of the reticulin stain should be assessed by detection of normal staining in vessel walls as internal control. The degree of myelofibrosis should be assessed by disregarding lymphoid nodules and vessels and disregarding fibers framing adipocytes. Areas of prominent scleredema or scarring should be included in the overall grading of myelofibrosis. Fiber density should be assessed in hematopoietic areas.

Approximately 30% to 50% of patients with PMF have karyotypic abnormalities at diagnosis. It is important to perform cytogenetic analysis on this patient population to exclude rare cases of chronic myelogenous leukemia with associated BM fibrosis. Detection of a Philadelphia chromosome or *BCR-ABL1* fusion gene is diagnostic of CML and excludes the diagnosis of PMF. In cases that are Philadelphia chromosome negative, it is prudent to perform FISH or polymerase chain reaction analysis for *BCR-ABL1*.

Because of BM fibrosis, it is often difficult to obtain optimal numbers of metaphase cells for cytogenetic analysis. In the past, a substantial percentage of patients with PMF had a "dry tap" or were uninformative, thereby making cytogenetic analysis challenging. Although cytogenetic analysis of PMF remains time consuming and laborious, cytogenetic studies are now informative in about 99% of patients from unstimulated peripheral blood specimens. This success is due to the presence of large numbers of immature hematopoietic cells (including CD34-positive cells) present in the peripheral blood combined with the use of an MPN interphase FISH panel that allows for essentially all PMF patients to be examined for the most frequent cytogenomic changes (see Figure 67-3). There is a high concordance rate (92%) between conventional cytogenetics and interphase FISH for the 12 most frequent chromosomal abnormalities detected in PMF. Although detection of clonal chromosomal abnormalities in a small proportion of metaphase, but not interphase cells, is a rare observation (≈2% of all patients), it demonstrates the importance of applying both technologies when evaluating PMF patients at diagnosis.

Among the Philadelphia chromosome-negative MPNs, PMF has the highest rate of chromosomal abnormalities at diagnosis. Deletions of the long arms of chromosomes 13 and 20, trisomy 8 and abnormalities of chromosomes 1, 7, and 9 constitute more than 80% of all chromosomal changes detected in PMF (Fig. 69-2). None of these lesions are specific for PMF because they are also detected in PV, ET, MDS, and other myeloid malignancies. Deletion of the long arm of chromosome 13 is substantially more frequent in PMF than in PV. Fine FISH mapping has defined the commonly deleted region to 13q13.3-q14.3 encompassing *RB1, D13S319,* and *D13S25* loci. As mentioned in Chapter 67, del(20q) and +9/+9p are more frequent in PV than in PMF. Multiple copies of 9p result in trisomy/tetrasomy or amplification of *JAK2* and each of these abnormalities has been reported in PMF. A 2.7-Mb region on chromosome 20, spanning D20S108 (proximal) and D20S481 (distal) is deleted in all Philadelphia chromosome–negative MPNs. A different region is deleted in other myeloid malignancies, but a common 1.6 kb region may constitute the major site responsible for loss of heterozygosity. High resolution SNP array karyotyping recently identified a novel 20p13 amplification in 55% of 20 patients at the time of PMF diagnosis. Within this band, *SIRPB1* gene locus is present in four copies. Currently, the role of *SIRPB1* gene in PMF remains unknown.

With disease progression from PV/ET to MF, the frequency of cytogenetic abnormalities increases to 70% to 90%. The types of chromosomal abnormalities observed in these cases are similar to those seen at diagnosis of PV/ET or PMF, but through subclonal evolution, they may become very complex. The number of genomic alterations are more than two or three times greater in the blast phase as in the chronic phase. Specific regions on 12p *(ETV6),* 17p *(P53),* and on 21q *(RUNX1)* are frequently altered and associated with disease progression.

Investigation of PMF by a comparative genomic hybridization technique suggests that genomic aberrations are much more common than has been previously indicated by conventional cytogenetic analysis and occur in the majority of cases. Gains of 9p were the most frequent finding, occurring in 50% of patients, suggesting that genes on 9p may play a crucial role in the pathogenesis of PMF. This

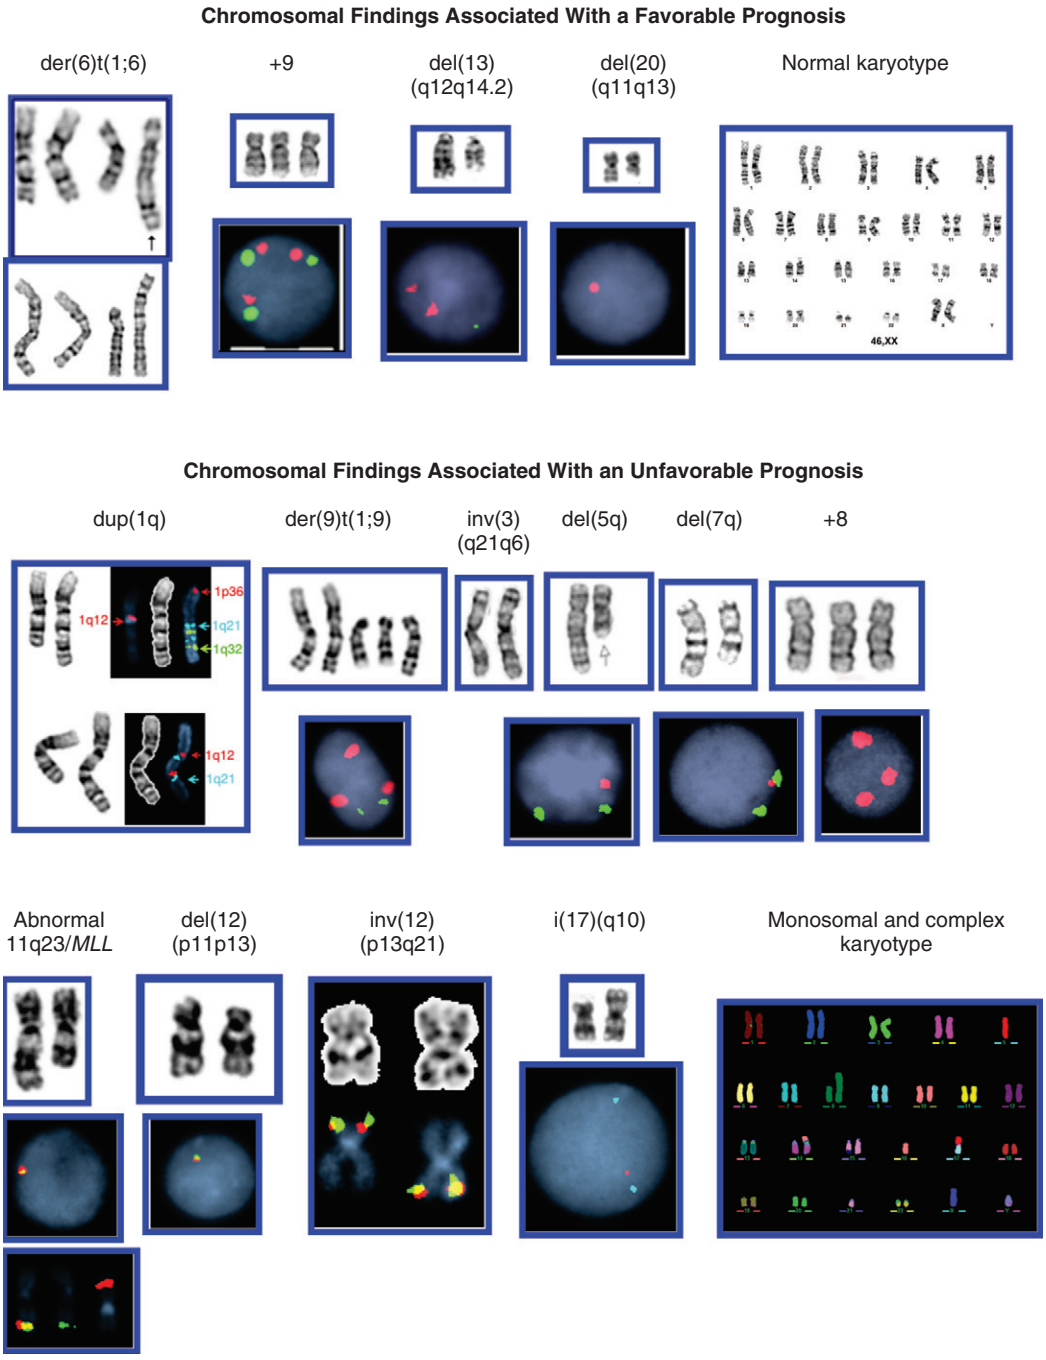

Figure 69-2 CYTOGENETIC FINDINGS IN PRIMARY MYELOFIBROSIS (PMF). The *top row* shows chromosomal abnormalities and corresponding interphase fluorescence in situ hybridization (FISH) findings associated with a favorable prognosis. They include unbalanced translocations between chromosomes 1 and 6 (both the short and long arms of chromosome 6) resulting in a gain of 1q, sole abnormality of chromosomes 9, 13, and 20 as well as the normal karyotype. Abnormalities include a gain of chromosome 9 and interstitial deletions of the long arm of chromosome 13 and 20. The *bottom row* shows chromosomal abnormalities and corresponding interphase nuclei after FISH studies associated with an unfavorable prognosis. They include duplication and trisomy 1q. The most frequent abnormality associated with polycythemia vera–related PMF is der (9)t(1;9), resulting in a gain of 1q *(red)* and 9p. Inversion of chromosome 3, -5/del(5q) *(red)* and -7/del(7q) *(red)* are rare in PMF as are rearrangement of 11q23 and deletion of the short arms of chromosome 12. Sole trisomy 8 is a frequent abnormality associated with PMF, and rearrangements of 12q are almost exclusively identified in PMF. The chromosomal abnormalities associated with the most dismal prognosis are heterozygous 17p loss *(red)* and monosomal or complex karyotype.

observation, together with the observation that loss of heterozygosity at 9p was a frequent stem cell defect in PV, served as a foundation for the discovery of the JAK2*V617F* mutation in MPN.

In PMF, the proportion of patients with the JAK2*V617F* mutation in granulocytes has been reported to range from 35% to 95%. The detection rate for JAK2V617F is much higher for patients with post-PV MF (91%) than PMF (45%) or post-ET MF (39%). In PV, a high burden of JAK2V617F allele has been associated with an increased rate of evolution to MF. Such wide differences in the mutational frequencies can be attributed to the different sensitivity of the

techniques used to detect the mutation and to differences in the case mix of the reported series (i.e., proportion of primary and secondary PMF cases). The JAK2V617F mutation in PMF is associated with an older patient age at diagnosis and a history of thrombosis or pruritus. The clinical utility of performing mutational studies in patients with PMF has been well defined in making a definitive diagnosis of PMF. More recently, a common JAK2 germline haplotype (46/1) that is identified by the rs12343867 SNP was found to affect disease susceptibility in PMF regardless of JAK2 mutational status. In a study of 130 PMF patients, the 46/1 haplotype was found in both JAK2V617F-positive and -negative cases at a frequency of 50% and 36%, respectively. Nullizygosity for the JAK2 46/1 haplotype (rs12343867 TT genotype) was found to be associated with a shortened survival in PMF, and this was independent of other clinical parameters or karyotype. This has led the authors to propose that the non-46/1 haplotypes may be associated with a more biologically and thus clinically aggressive form of PMF.

Gain-of-function mutations of the thrombopoietin receptor, MPLW515L and MPLW515K, are present in patients with PMF at a frequency of approximately 5%, 1% of patients with ET but not patients with PV. MPL mutations may occur concurrently with the normal V617F mutation, suggesting that these alleles may have functional complementation in MPN. In all cases, the MPLW515K/L mutant allele is present in excess of the JAK2V617F allele. In contrast to acute myeloid leukemia (AML), mutations in the receptor tyrosine kinases KIT, FMS, and FLT3 have not been documented in PMF.

The number of circulating cells expressing the CD34 antigen, a phenotypic marker of hematopoietic stem and progenitor cells, in patients with PMF has been reported to be more than 300 times higher than in normal volunteers and 18 to 30 times higher than in patients with PV or ET. The clinical utility of the cytofluorimetric measurement of $CD34^+$ cells as a diagnostic marker of PMF is hampered by the fact that a small number of subjects with PMF exhibit a normal number of $CD34^+$ cells in the peripheral blood. Cases with a very mild disease phenotype or absent or slight reticulin BM fibrosis account for the majority of these patients. High values of $CD34^+$ cells ($>200 \times 10^6$/L) have been proposed as an indicator of an accelerated phase of the disease.

On radiographic examination, the characteristic features of PMF are a diffuse increase in bone density and increased prominence of the bony trabeculae. This increased bone density may be patchy and can produce a mottled appearance. Such abnormalities have been reported in 25% to 66% of patients with PMF.

Noninvasive imaging of BM is a promising means of evaluating the BM cellularity and distribution in PMF. Magnetic resonance imaging (MRI) can portray the conversion or reconversion of fatty to cellular BM. Fibrotic BM is easily distinguished from cellular BM by its strikingly low signal intensity with all pulse signals. The BM patterns in the proximal femurs of PMF patients have been reported to be correlated with the clinical severity of the disease. BM MRI has been used to differentiate PMF from ET, where the BM adipose tissue is preserved, but in PMF, the adiposity of the BM is reduced.

DIFFERENTIAL DIAGNOSIS

A patient with hepatosplenomegaly, peripheral cytopenias, teardrop poikilocytosis, leukoerythroblastosis, and BM fibrosis probably has PMF, but other disorders may also lead to this clinical picture (see Table 69-3 and Fig. 69-3). The WHO diagnostic criteria were revised,

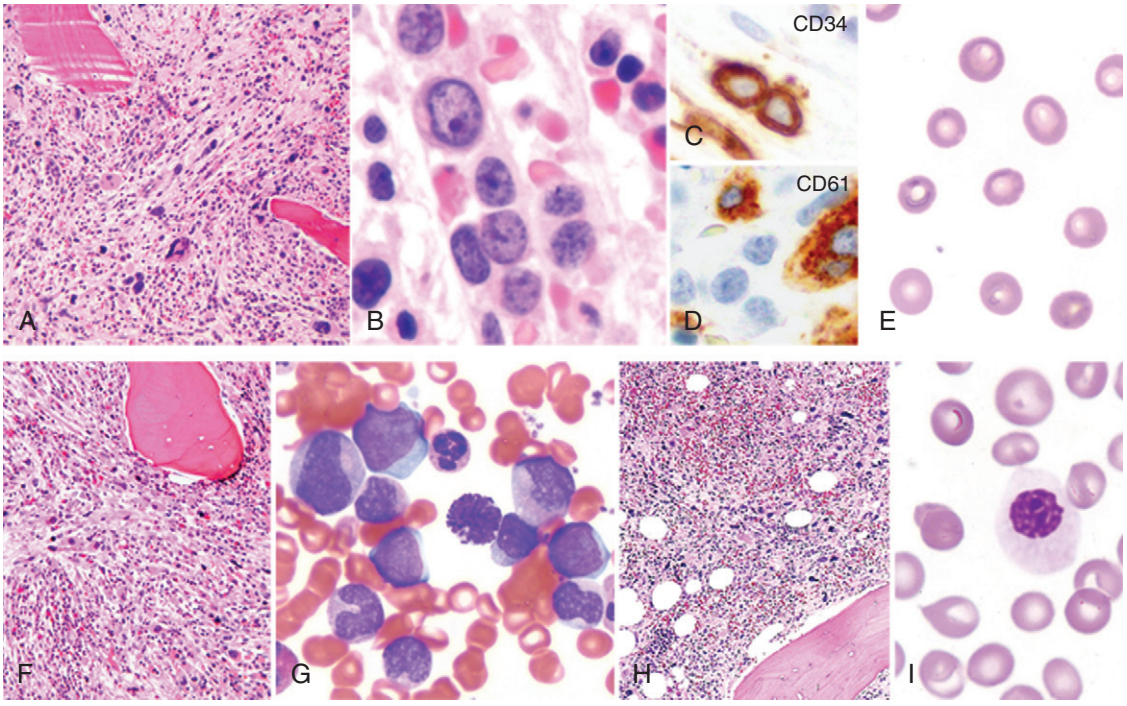

Figure 69-3 DIFFERENTIAL DIAGNOSTIC CONSIDERATIONS IN PRIMARY MYELOFIBROSIS (PMF). **A** to **E,** Acute panmyelosis with myelofibrosis (APMF). **F** and **G,** Chronic myelogenous leukemia (CML) in an advance phase with fibrosis. **H** and **I,** Myelodysplastic syndrome (MDS) with fibrosis. The bone marrow (BM) biopsy of APMF, CML in advanced phase with fibrosis, and MDS with fibrosis can all look similar to PMF at low power (**A, F,** and **H**). In APMF, the distinction from PMF is made in part by seeing increased immature cells on the biopsy **(B)** interspersed with other hematopoietic precursors. These are usually $CD34^+$ **(C)** but in contrast to acute megakaryoblastic leukemia are usually CD61 negative **(D).** Also, the peripheral blood usually shows pancytopenia with neither teardrop red blood cells nor a leukoerythroblastosis **(E).** Although the biopsy of CML presenting in an advanced phase can resemble PMF **(F)**, the peripheral blood usually shows a classic granulocytosis with left shift and basophilia **(G)**. In the case illustrated, the 30-year-old female patient had fibrotic BM **(F)** but presented with a white blood cell count of 148,000/L showing a full spectrum of granulocytes, increased blasts (22%), and basophilia. P210 *BCR/ABL1* was demonstrated. The bone marrow biopsy in MDS with fibrosis has small megakaryocytes **(H)**, but dysplasia is otherwise difficult to evaluate in the absence of an aspirate, and one must rely on the peripheral blood to identify dysplasia, as in the severely dysplastic neutrophil **(F)**.

incorporating testing for JAK2V617F and activating MPL mutations as well as greater emphasis on histomorphologic criteria which allow one to distinguish early phases of PMF from ET (Table 69-5). The WHO criteria are based on the recognition of a prefibrotic form of PMF without reticulin fibrosis and that the primary diagnostic features of PMF are increased megakaryocyte numbers, megakaryocyte morphology, and abnormalities of granulocyte mutation. Secondary MF frequently occurs in patients with lymphoma or metastatic carcinoma of the stomach, prostate, lung, or breast. The clinician should be extremely careful in making the diagnosis of PMF in a patient who has a history of a primary neoplasm. Demonstration of carcinoma cells in the BM establishes that metastatic carcinoma is the cause of the BM fibrosis. Careful breast examination and mammography are indicated in all women suspected of having PMF to exclude the possibility of metastatic breast cancer. The finding of blastic or lytic bone lesions in patients with MF suggests the presence of an underlying carcinoma. Disseminated tuberculosis and histoplasmosis have been associated with the development of secondary MF. Caseating or noncaseating granulomas observed on BM biopsy suggest the presence of these infectious disorders. Identification of the causative organisms by culture techniques should be pursued.

A number of other primary hematologic disorders can also be accompanied by BM fibrosis. A variety of overlap syndromes that share features of both PMF and MDS have been reported and are seen frequently in clinical practice. These so-called overlap syndromes have pathological and clinical features of both MPN and MDS and are characterized by BM hypercellularity, dysplasia of various myeloid lineages, and proliferative features yet also ineffective hematopoiesis, modest hepatosplenomegaly, and some degree of BM fibrosis. These patients are occasionally JAK2V617F positive and frequently have TET2 mutations. Such patients frequently present with cytopenias and are at a high risk of developing acute leukemia. These cases indicate the limitations of adhering to strict disease classifications and underscore that a continuum exists between MPNs and MDS. The peripheral blood and BM findings that allow differentiation of these disorders and can be enhanced by JAK2V617F and MPLW515L/K mutational analysis. Patients with the variant MDS with MF frequently present with cytopenias and have dysplastic cellular abnormalities indistinguishable from those of other patients with myelodysplasia. Their BMs, however, are characterized by the presence of BM fibrosis and a striking megakaryocytic hyperplasia, with a predominance of small hypolobulated forms, in some cases surrounding fibrosis. Reticulocytopenia is characteristic of these patients, as are teardrop RBCs and a clinical picture of leukoerythroblastosis. Unlike patients with PMF, patients with myelodysplasia and BM fibrosis do not have hepatic or splenic enlargement extending more than 3 cm below the costal margin. The overall survival time of patients with this variant of myelodysplasia has been reported to be 30 months, with death resulting from the effects of cytopenias or transformation to acute leukemia. Additional studies have indicated that the presence of MF in patients with myelodysplasia was associated with a particularly short survival time (9.6 months) compared with patients with myelodysplasia without fibrosis (17.4 months).

Hairy cell leukemia can also be confused with PMF. In one study, five of 61 patients who had originally been diagnosed as having PMF were shown retrospectively to have had hairy cell leukemia. Hairy cell leukemia can present as pancytopenia with splenomegaly and is associated with a dry BM tap. In one series, BM reticulin content was increased in 26 of 29 patients with hairy cell leukemia. The presence of hairy mononuclear cells possessing tartrate-resistant acid phosphatase or the appropriate phenotype in the peripheral blood or BM should facilitate differentiation of PMF from hairy cell leukemia (see Chapter 77). This exercise is important because of the different modalities of treatment that can be successfully used for hairy cell leukemia.

Bone marrow fibrosis can occur in patients with other MPNs, especially PV and CML, and less frequently with ET. In CML, progressive BM fibrosis may herald the onset of accelerated disease or blast crisis. MF in CML occurs in two distinct patterns, one in which patients present with CML and significant associated BM fibrosis and a second in which the MF develops late in the course of the CML. The MF in the latter group appears at a mean of 36 months after the diagnosis of CML, is associated with a mean survival time of 4.9 months from the detection of MF, and therefore represents an ominous prognostic sign.

Post-PV MF occurs in 5% to 15% of patients with PV. This transition occurs, on average, 10 years after the initial diagnosis of PV is made, but in individual cases, it may appear after shorter or longer intervals. PMF is clinically indistinguishable from post-PV MF except for the previous history of erythrocytosis in the latter group. Of patients with post-PV MF, 25% to 50% develop leukemia, and 70% are dead within 3 years of this transition. Post-PV MF represents a transitional myeloproliferative syndrome with relatively grave prognostic implications. MF has also been reported after ET. These investigators claimed that these patients did not represent individuals with prefibrotic stages of PMF but rather evolution of patients with true ET. They estimated the probability of developing such a complication to be 3% 5 years after diagnosis, 8% at 10 years, and 15% at 15 years, and considered this evolution to BM fibrosis a major long-term complication of ET. This evolution of ET was reported not to be associated with or prevented by the use of cytotoxic agents. Others have, however, suggested that most individuals with a presumptive diagnosis of ET whose disease evolved into post-ET MF had prefibrotic PMF if strict diagnostic criteria were used. They have conjectured that a considerable number of patients who carry a

Table 69-5 Proposed Revised World Health Organization Criteria for Primary Myelofibrosis*

MAJOR CRITERIA

1. Presence of megakaryocyte proliferation and atypia,† usually accompanied by either reticulin or collagen fibrosis, or, in the absence of significant reticulin fibrosis, the megakaryocyte changes must be accompanied by an increased bone marrow cellularity characterized by granulocytic proliferation and often decreased erythropoiesis (i.e., prefibrotic cellular-phase disease)
2. Not meeting WHO criteria for PV,‡ CML,§ MDS,‖ or other myeloid neoplasm
3. Demonstration of *JAK2*617V >F or other clonal marker (e.g., *MPL*515W >L/K) or in the absence of a clonal marker, no evidence of bone marrow fibrosis caused by underlying inflammatory or other neoplastic diseases¶

MINOR CRITERIA

1. Leukoerythroblastosis**
2. Increase in serum lactate dehydrogenase level**
3. Anemia**
4. Palpable splenomegaly**

Data from Tefferi A, Thiele J, Orazi A, et al: Proposals and rationale for revision of the World Health Organization diagnostic criteria for polycythemia vera, essential thrombocythemia, and primary myelofibrosis: Recommendations from an ad hoc international expert panel, *Blood* 110:1092, 2007.
CML, Chronic myeloid leukemia; *MDS,* myelodysplastic syndrome; *PV,* polycythemia vera; *WHO,* World Health Organization.
*Diagnosis requires meeting all three major criteria and two minor criteria.
†Small to large megakaryocytes with an aberrant nuclear-to-cytoplasmic ratio and hyperchromatic, bulbous, or irregularly folded nuclei and dense clustering.
‡Requires the failure of iron replacement therapy to increase hemoglobin level to the polycythemia vera range in the presence of decreased serum ferritin. Exclusion of polycythemia vera is based on hemoglobin and hematocrit levels. Red blood cell mass measurement is not required.
§Requires the absence of *BCR-ABL.*
‖Requires the absence of dyserythropoiesis and dysgranulopoiesis.
¶Secondary to infection, autoimmune disorder or other chronic inflammatory condition, hairy cell leukemia or other lymphoid neoplasm, metastatic malignancy, or toxic (chronic) myelopathies. It should be noted that patients with conditions associated with reactive myelofibrosis are not immune to primary myelofibrosis, and the diagnosis should be considered in such cases if other criteria are met.
**Degree of abnormality could be borderline or marked.

diagnosis of ET already are actually in a prefibrotic phase of PMF. Careful prospective natural history studies using strict histopathologic criteria are still required to resolve this controversy.

Acute panmyelosis with myelofibrosis (APMF) represents a clinical entity distinct from PMF. This disorder has also been termed acute MF, acute myelosclerosis, acute megakaryocytic MF, and acute myelodysplasia with MF. APMF is exceedingly rare and corresponds to fewer than 1% of the cases of AML. Patients characteristically present with pancytopenia, fever, absence of clinically significant splenomegaly, minimal or absent teardrop poikilocytosis, and fibrotic BM. The BM is characterized by the appearance of immature myeloid cells and the blast cells, which frequently express megakaryocytic phenotypic properties. Survival ranges from 1 to 9 months after diagnosis. Its distinction from PMF is important because aggressive chemotherapy and possibly SCT are the treatments of choice. Even though some authors consider APMF a form of acute megakaryoblastic leukemia (AMKL), the WHO criteria for diagnosing APMF are somewhat distinct from those for AMKL. The main requirement for the diagnosis of AMKL is a minimum of 20% BM blasts, a percentage that is significantly higher than observed in APMF. In addition, the blasts in all cases of AMKL stain strongly for CD61 and CD41 and are negative for myeloperoxidase. In contrast, APMF is characterized by a lower percentage of blasts within a polymorphic cellular background, which includes erythroblasts, megakaryocytes, and maturing myeloid elements with variability in their relative proportions from case to case. The blasts in APMF did not express significant reactivity to megakaryocytic phenotypic markers but are identifiable by their strong reactivity with CD34 and occasional reactivity with myeloperoxidase. These results emphasized the panmyelotic nature of APMF. In PMF, the peculiar cytologic characteristics of the megakaryocytes, which include anisocytosis with a predominance of large size forms arranged into tight cellular clusters, the abnormal chromatin clumping with hyperchromatic nuclei and clumped (cloud shape) nuclear lobulation as well as the characteristic stromal changes that include the presence of intrasinusoidal hematopoiesis, allow for a distinction from these more acute disorders.

Up to 12% of patients who present with MF have been reported to have an underlying autoimmune disorder such as SLE, although in the authors' clinical practice, this is an extraordinary rare event. Primary autoimmune MF (primary AIMF) likely represents a distinct clinicopathologic syndrome unrelated to other well-defined autoimmune disorders. Eight diagnostic criteria for AIMF, including grade 3 or 4 reticulin fibrosis in the BM, lack of clustered or atypical megakaryocytes, lack of dysplasia or eosinophilia or basophilia, lymphoid infiltration of the BM, lack of osteosclerosis, absent or mild splenomegaly, presence of autoantibodies, and absence of disorders associated with MF, have been outlined. The appearance of the BM in AIMF is indistinguishable from that of PMF. Autoimmune MF occurs predominantly in females with a broad clinical spectrum. Patients may present with MF in the setting of established SLE or in patients with minimal manifestations of an autoimmune disorder as in primary AIMF. The presence of teardrop erythrocytes or leukoerythroblastosis in a patient with lupus suggests autoimmune MF. Such patients universally have a positive ANA test result or an elevated anti-DNA titer. Because the physical manifestations of an autoimmune disease may not be evident, all patients with MF should have an ANA test to exclude an autoimmune etiology. Moreover, a diagnosis of AIMF is important because the cytopenias and BM fibrosis in this disorder may partially resolve with steroid or methotrexate therapy. However, it must be pointed out that the place of primary AIMF in the classification of fibrotic disorders needs a more precise definition requiring the absence of mutations that include JAK2V617F, MPLW515L, and MPLW515K.

PROGNOSIS

The median overall survival period from the time of diagnosis of PMF varies from series to series but is approximately 5 years (Fig. 69-4). Individual survival times have been reported to range from 1 year to more than 30 years. The primary causes of death include infection, leukemic transformation, heart failure, bleeding, hepatic failure caused by EMH of the liver, portal hypertension, renal failure, pulmonary embolism, and posttransplantation. The incidence of acute leukemia as a terminal event ranges from 5% to 22%, depending on the series cited (Fig. 69-5). Approximately half of the patients who develop acute leukemia have not received previous treatment

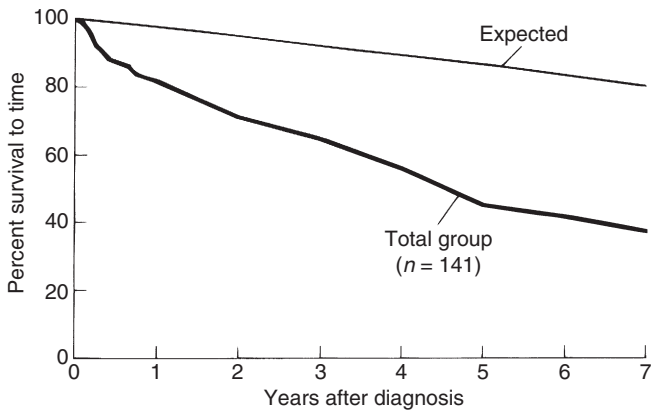

Figure 69-4 OVERALL SURVIVAL FROM THE TIME OF DIAGNOSIS OF 141 PATIENTS WITH PRIMARY MYELOFIBROSIS. *(Data from Silverstein MN:* Agnogenic myeloid metaplasia*, Acton, MA, 1975, Publishing Sciences Group, p 197.)*

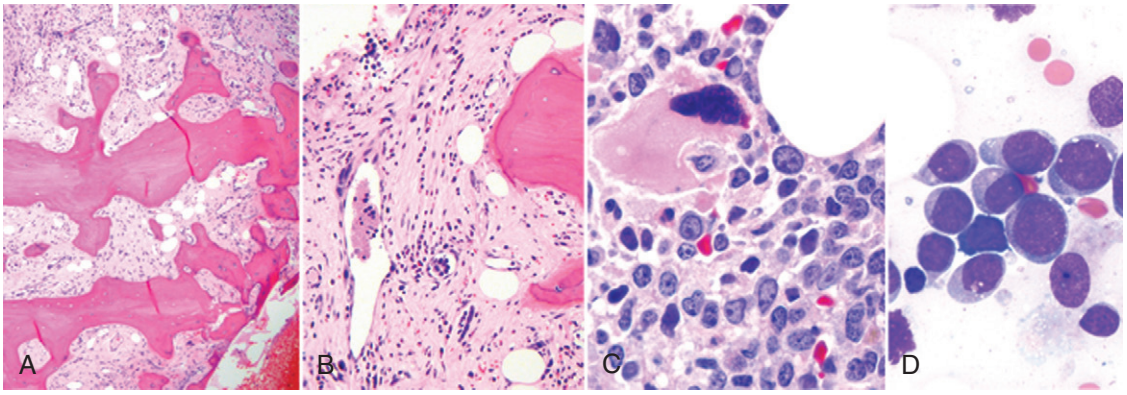

Figure 69-5 DISEASE PROGRESSION IN PRIMARY MYELOFIBROSIS (PMF). Marked osteosclerosis (**A** and **B**) and acute leukemia (**C** and **D**). In some patients, PMF progresses to severe osteosclerosis in which there is markedly thickened and irregular bone formation **(A)** and a bone marrow space that is fibrotic and nearly depleted of hematopoietic elements **(B).** A terminal transformation to acute leukemia (**C** and **D**) occurs in 5% to 22% of cases.

with alkylating agents or radiotherapy, suggesting that the evolution into acute leukemia may be part of the natural history of PMF. The actuarial cumulative risk of death from leukemic transformation at 1 and 5 years after diagnosis has been reported to be 2% and 16%, respectively. Immunologic and morphologic characterization of the blast phenotypes comprising these leukemias reveals that a typical myeloid phenotype is most commonly detected; other cell lineages, such as megakaryocytic, erythroid, lymphoid, and even stem cell phenotype, may also be involved, leading to the existence of mixed myeloid and hybrid transformations. Megakaryoblastic transformations have been detected in one-third of cases in one series, an incidence higher than that found in de novo AML. In 50% of cases of JAK2V617F MPNs, the blast cells that represent the progeny of the leukemia initiating clone are JAK2V617F negative suggesting that the leukemia originates from a clone distinct from the JAK2V617F-positive clone. This coexistent JAK2V617F-negative clone appears to have a higher propensity to undergo leukemic transformation. JAK2V617F therefore does not appear to be a prerequisite for leukemic transformation of MPNs, suggesting that additional genetic events are required for full transformation to occur. SNP array analysis has shown that genomic alterations occur at an increased frequency during the period of blastic transformation and that no single gene or molecular pathway is sufficient to cause transformation. A surprising correlation has been observed between the phenotype of the preceding MPN and the JAK2 mutational status of the leukemic blasts after transformation. In contrast to JAK2 WT AML in this setting, evolution to JAK2V617F leukemias is invariably preceded by a myelofibrotic transformation of ET or PV or PMF. Because of these observations, myelofibrotic transformation of ET or PV are thought by many to represent an accelerated phase of the initial MPN preceded by genetic changes that result in evolution to MF and eventually leukemia. JAK2 WT leukemia by contrast usually arises in patients with chronic phase PV or ET that do not undergo evolution to MF. Some have suggested that these leukemias are therapy related and are a consequence of radioactive phosphorous, pipobroman, or hydroxyurea administered during the chronic phase. The reversion from JAK2V617F to WT JAK2 in these leukemias has been shown not to be caused by homologous recombination. Two models have been proposed to account for the clonal relationship between JAK2 WT AML and its preceding MPN: (1) Both the chronic MPN and the AML arise from a shared pre-JAK2V617F founder clone, and (2) the chronic MPN and the AML arise from two independent stem cells (Fig. 69-6).[11] It remains possible that each model is viable and operates in different individual patients. Survival after blast transformation is limited, a phenomenon that is probably a result of patient age and the aggressive biology of these leukemias. Leukemic transformation of PMF has been reported to be fatal in 98% after a median of 2.6 months. Successful leukemia remission induction therapy in these patients is an extremely rare event. Patients should therefore be sent for stem cell transplant before leukemic transformation.

Several clinical and biologic parameters that are characteristic of patients at diagnosis have been used to identify subgroups of patients with different outcomes. Some investigators have suggested that there are two subpopulations of patients in PMF: short-lived and long-lived subpopulations of patients. Such efforts at developing prognostic parameters have met with conflicting results, with the exception that anemia at presentation is consistently associated with short survival. Dupriez and associates developed an extremely simple scoring system, the Lille scoring system, based on two adverse prognostic factors—hemoglobin level less than 10 g/dL and WBC count less than 4000/mm^3 or more than 30,000/mm^3 and were able to stratify patients into three groups The low-risk (zero factors), intermediate-risk (one factor), and high-risk (two factors) groups were associated with median survival times of 93, 26, and 13 months, respectively. Other scoring systems that use simple clinical hematologic parameters have been subsequently proposed. In another study, the presence of a hemoglobin level of 10 g/dL or higher, a platelet count of at least 100×10^9/L, and less than 3% circulating blasts predicted a median survival of approximately 15 years compared with less than 5 years in the remaining patients.

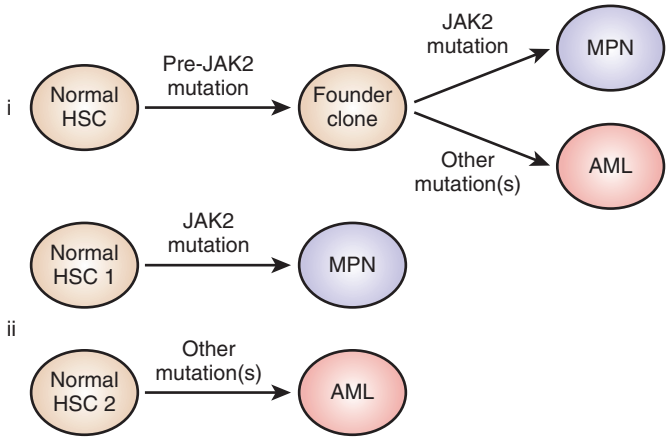

Figure 69-6 MODELS TO EXPLAIN PROGRESSION FROM A JANUS KINASE 2 (JAK2) MUTANT MYELOPROLIFERATIVE NEOPLASM TO A JAK2 WILD-TYPE LEUKEMIA. In model 1 (i), the two phases of disease are phylogenetically related, having arisen from a shared (pre-JAK2) founder clone, but in model 2 (ii), the two phases of disease are clonally unrelated, reflecting transformation of independent stem cells. *AML,* acute myeloid leukemia; *HSC,* hematopoietic stem cell. *(From Beer PA, Delhommeau F, LeCouédic JP, et al: Two routes to leukemic transformation after a JAK2 mutation-positive myeloproliferative neoplasm.* Blood *115:2891, 2010.)*

The International Working Group for Myelofibrosis Research and Treatment (IWG-MRT) developed an international prognostic scoring system (IPSS) based on 1054 patients diagnosed with PMF.[12] (Table 69-6 and 69-7) compare four validated prognostic scoring systems for patients with PMF. The overall median survival for this group was 69 months, and multivariate analysis identified age older than 65 years, presence of constitutional symptoms, hemoglobin below 10 g/dL, leukocyte count above 25×10^9/L, and peripheral blood blasts 1% or greater as significant risk factors. The sum of the risk factors allows for allocation into discrete risk groups. Four risk groups can be discerned with non-overlapping survival curves based on this model with median survivals of 135, 95, 48, and 27 months for low (0), intermediate-1 (1), intermediate-2 (2), and high-risk (3-5) groups, respectively. Although the presence of JAK2V617F was associated with age older than 65 years, it did not influence survival in this study. The presence of cytogenetic abnormalities exerted an influence on the intermediate risk groups only. A cohort of 525 PMF patients was followed over time to assess the prognostic influence of the five IPSS clinical variables acquired during the course of disease rather than at presentation. The IPSS variables were analyzed as time-dependent covariates in a multivariate Cox proportional hazard model. Anemia was found to have the most significant hazard ratio for survival. The advantage of this dynamic IPSS (DIPSS) is the ability to assess real-time prognosis as a patient acquires each clinical feature. An age-adjusted DIPSS (aaDIPSS) was also proposed for patients younger than the age of 65 years and may be particularly useful when applied to young patients in the context of risk assessment for SCT. Most recently, an attempt to further refine the DIPSS based on the incorporation of unfavorable karyotype, platelet count below 100×10^9/L and transfusional status within the scoring system was reported. Additionally, in this review of 793 PMF patients, a poorer, leukemia-free survival was predicted by the presence of thrombocytopenia or unfavorable karyotype with a 10-year risk of 31% (hazards ratio [HR], 3.3; 95% confidence interval [CI], 1.9-5.6).

Although cytogenetic studies are an integral part of a variety of prognostic scoring systems for many hematologic malignancies, for similar purpose in PMF, this has not been as well developed. However, substantial progress has been made during the past few years to allow for the use of cytogenetics as a prognostic indicator. Initially, a group from MD Anderson performed a retrospective analysis of 256 patients (36% had an abnormal karyotype) and determined that baseline cytogenetic status was useful in predicting survival. Sole deletions of

Table 69-6 Prognostic Scoring Systems for Primary Myelofibrosis

Risk Factor	Lille	IPSS	DIPSS	DIPSS Plus
Anemia (hemoglobin)	X (<10 g/dL)	X (<10 g/dL)	X (<10 g/dL)	X (<10 g/dL)
Leukocytosis (white blood cell count)	X (<4 or >30 x 10^9/L)	X (>25 x 10^9/L)	X (>25 x 10^9/L)	X (>25 x 10^9/L)
Peripheral blood blasts		X (≥1%)	X (≥1%)	X (≥1%)
Constitutional symptoms		X	X	X
Age (years)		X (>65)	X (adjusted for age)	X
Karyotype				X (unfavorable*)
Platelet				X (<100 x10^9/L)
Transfusion status				X

DIPSS, Dynamic international prognostic scoring system; *IPSS,* international prognostic scoring system.
*Unfavorable karyotype includes complex or sole or two abnormalities that include +8, -7/7q-, i7/7q-, i(17q), -5/5q-, 12p-, inv(3), or 11q23 rearrangements.

Table 69-7 Median Survival of Each Risk Group in Four Prognostic Scoring Systems for Primary Myelofibrosis

Risk Group	Lille	IPSS	DIPSS	DIPSS Plus
Low	93 months	135 months	Not reached	185 months
Intermediate-1	26 months	95 months	170 months	78 months
Intermediate-2		48 months	48 months	35 months
High	13 months	27 months	18 months	16 months

DIPSS, Dynamic international prognostic scoring system; *IPSS,* international prognostic scoring system.

chromosomes 13 and 20 or trisomy 9 alone or in the presence of other abnormalities were associated with a median survival time similar to those with a normal karyotype (63 and 46 months, respectively). By contrast, abnormalities of chromosomes 5 or 7 or three or more abnormalities were associated with a median survival time of 15 months. In the more expanded Mayo Clinic study of 433 patients, a two-tier cytogenetic risk stratification after a median follow-up of 4 years was established.[13] Because cytogenetic analysis is not yet incorporated in the IPSS, the following cytogenetic current schema should be carefully considered.[14] Patients with favorable karyotype include sole chromosome 1 translocations or duplication, del(13q), del(20q), trisomy 9, other sole abnormalities, two abnormalities excluding unfavorable type, and a normal karyotype. A 5-year survival rate was 51% with a median survival of 5.2 years was observed (see Fig. 69-5). The 5-year survival for patients with an unfavorable karyotype, including a sole trisomy 8, sole abnormalities of chromosomes 5 or 7, inversion of chromosome 3, isochromosome 17q, deletion 12p or 11q23 rearrangement as well as two abnormalities including the unfavorable type and a complex karyotype was 8% with a median survival of 2 years. Moreover, multivariable analysis demonstrated that karyotype ($P = .001$) and platelet count ($100 << 10^9$/L [$P = .04$]) but not IPSS ($P = .27$) predicted leukemia-free survival: the 5-year leukemic transformation rates for unfavorable versus favorable karyotype were 46% and 7%, respectively ($P < .0001$). The implementation of these recommendations observations needs confirmation from multiple institutions. Specifically, gain of chromosome 1q, occurring in 22% of PMF, is believed to be associated with disease progression, and jumping 1q translocations was reported to be associated with imminent transformation to AML in a majority of patients. In PMF, the region on chromosome 1 that is most frequently duplicated or occurring in trisomy is between 1q21-32 and 1q32-44 band regions (see Fig. 69-3). This 1q region has been reported in unbalanced translocations with many chromosomes, although more specific PMF translocation involves der(6)t(1;6)(q21-23;p21-23 or q27). In contrast, in patients with PV-related MF, the most frequent recurrent 1q abnormality involves der(9)t(1;9)(q21;q12), resulting also in trisomy 9p. A new cytogenetic risk category, monosomal karyotype (MK), also defines an unfavorable risk category. An MK is defined as having two or more autosomal monosomies or a single autosomal monosomy associated with at least one structural abnormality. This is a rare cytogenetic change associated with median survival of 6 months and a 2-year leukemic transformation rate of 29.4%. At diagnosis of PMF, detection of MK is associated with extremely poor overall and leukemia-free survival.

Patients who have normal diploid karyotype at baseline that remains unchanged during the period of observation have a similar median survival to those with favorable abnormalities (36 vs. 31 months, respectively). The most unfavorable cytogenetic abnormalities include i(17q), which results in the loss of 17p, and heterozygous loss of P53, inversion of chromosome 3 and MK.

Most studies have indicated that the overall survival of patients with JAK2V617F-positive and -negative PMF are similar; however, patients with JAK2V617F-positive disease and a low allele burden (<25%) have been shown to have a shorter survival time. In addition, mutations in MPL or TET2 do not appear to influence overall or leukemia-free survival. A number of investigators have attempted to correlate the presence of a variety of more recently identified mutations with disease outcomes of patients with PMF. EZH2 mutations have been identified in 6% of patients with PMF, 3% of PV patients, 3% of patients with post-PV MF, and 9.4% of patients with post-ET MF. More than 40% of the patients with EZH2 mutations were JAK2V617F, 6% have a TET2 mutation, and, 22% harbored an ASXL mutation. Concurrent EZH2 mutations and MPL mutations have not been observed. EZH2 mutations are usually present at the diagnosis of the chronic MPN and are maintained universally in the leukemic blasts at the time of transformation to AML. EZH2 mutated patients are characterized by more profound leukocytosis and larger spleens and have a higher percentage of blasts. The survival of patients with EZH2 mutations was clearly inferior because they clustered in patients with IPSS scores associated with high-risk disease. In addition, IDH mutations, albeit rare in PMF patients, have been associated with an inferior survival in JAK2V617F-positive patients, raising the possibility of the cooperation between IDH mutations and JAK2V617F in leukemic transformation.

Therapy

The optimal forms of treatment for PMF have not yet been defined, but reports of successful nonmyeloablative allogeneic SCT provide hope for cure of a subpopulation of these patients, and the recent approval of small molecule JAK2 inhibitors that are effective in reducing the degree of splenomegaly and alleviating systemic symptoms is

an important therapeutic advance. A conservative approach to management is generally accepted, with observation of asymptomatic patients and therapeutic intervention reserved for patients with symptoms.[15] Hydroxyurea appears to be a useful agent for the treatment of PMF. Its use has been associated with significantly reduced platelet numbers and a reduction of megakaryocytic abnormalities, as well as a significant reduction of MF. Some investigators have hypothesized that hydroxyurea-induced suppression of megakaryocytopoiesis causes a reduction in the levels of platelet-derived fibrogenic cytokines, resulting in reduced fibroblast proliferation and deposition of reticulin. Moderate doses (20-30 mg/kg) of hydroxyurea given twice or three times weekly are effective and safe in PMF patients requiring treatment. Similar reports have appeared after the use of daily busulfan with responding patients achieving hematologic remission and some reversal of BM fibrosis. Not only did hematologic parameters, including the hemoglobin and hematocrit levels, improve, but a reduction of the number of teardrop erythrocytes and the degree of leukoerythroblastosis has been reported in occasional patients. Most importantly, the quality of life of these individuals improved. Judicious use of busulfan is recommended in this setting, however, because of its potential for producing delayed BM suppression. Melphalan administered at low doses (2.5 mg given three times a week) has also been reported to be well tolerated and capable of producing less hematologic toxicity than busulfan. Among patients with severe anemia requiring transfusion therapy, 38% became transfusion independent, and 20% experienced a 50% reduction in their transfusion requirement. Approximately 54% of patients with symptomatic splenomegaly experienced a clinically significant reduction in spleen size. The median duration of the response to melphalan therapy was somewhat longer than 2 years. The disease of more than 20% of the patients receiving melphalan evolved into the leukemic phase. It is impossible to determine whether melphalan therapy played a role in this evolution or if this rate of blastic transformation was a consequence of the advanced stage of the disease at the time of treatment. The use of this agent was associated with acceptable toxicity, with only 13% of patients stopping their therapy because of the development of cytopenias and 17% requiring a dose reduction because of hematologic toxicity.

Interferon-α therapy has been reported to have activity in some patients with PMF. It can be useful in suppressing thrombocytosis and inhibiting the activity of PDGF, which stimulates the proliferation of fibroblasts.[16] A combination of INF, granulocyte-macrophage colony-stimulating factor (GM-CSF), and erythropoietin (EPO) in seven patients with an early form of PMF was investigated. Six of seven patients enjoyed marked reductions in spleen size. Each of these patients had an increase of 1 g/dL or more in the hemoglobin concentration. In one patient, the degree of BM fibrosis was diminished. These investigators suggested that INF might decrease the rate of fibrosis if administered chronically during the early course of this disease. Others have not reported similar effects in patients with more advanced phases of the disease. In one series, only four of 11 patients were able to complete 1 year of therapy; the other seven patients discontinued the drug because of unacceptable toxicity or the development of severe cytopenias. No clinically significant improvement was observed in any of these patients. INF therapy did not appear to alter the degree of BM fibrosis, osteosclerosis, or angiogenesis. A small phase II pilot study in PMF patients demonstrated responses in patients with prefibrotic hypercellular PMF treated with low doses of IFN-α-2b over an extended period (median duration, 3 years). Four patients with JAK2V617F-positive PMF were followed over time, and although all had clinical responses, only one had a significant reduction in mutant allele burden. The drug was generally well tolerated at doses between 1 and 2 million units weekly, and responses in the BM included reduction in reticulin fibrosis and abnormal cellular morphology. Eleven patients with PMF were treated with a pegylated form of INF-α-2b (PEG-IFNα-2b) at starting dose between 2 and 3 μg/kg/week; only a single patient with PMF responded. Although the pegylated form of this drug allows for weekly injections, the toxicity profile was found to be similar to the standard formulation and for many patients limits the duration of therapy. The most common grade 3/4 toxicity was fatigue and thrombocytopenia. Because of the recent encouraging results reported with PEG-IFN-α-2a (Pegasys) in PV patients, this form of INF-α has also been tested in MF patients. The French Groupe d'Etudes des Myelofibrosis (GEM) and France Intergroupe des Syndromes Myeloproliferatifs conducted a study of 18 patients with PMF and post-ET/PV MF treated with Pegasys.[17] Of the four PMF patients included in this study, one had a CR, two had a minor response, and one had no response by EUMNET criteria. Responses were associated with improvement in the degree of anemia, leukocytosis, and thrombocytosis but not splenomegaly and appeared to be irrespective of JAK2 status. Comprehensive reviews of the literature suggest that modest benefits may be derived from INF-α therapy for PMF after patients have entered the more advanced phases of the disease. Further large randomized studies are warranted in patients with the prefibrotic phase of PMF to determine the effects of this modality of treatment on disease-free survival, overall survival, quality of life, and progression to more advanced phases of PMF or evolution to acute leukemia. Before such trials are completed, INF therapy at any phase of PMF should be considered an experimental form of therapy and not embarked upon unless the patient is participating in a clinical trial.

Therapy is indicated for PMF patients with the following conditions: symptoms attributable to anemia, pressure symptoms related to splenomegaly, bleeding problems, life-threatening thrombocytopenia, significant hyperuricemia bone pain, systemic symptoms (fevers, night sweats and weight loss), and portal hypertension and life-threatening gastrointestinal bleeding. Hyperuricemia should be aggressively treated in all patients with PMF. Hydration and chronic administration of allopurinol (300 mg/day) are suggested.

Anemia is a common problem in patients with PMF. It is usually multifactorial in origin; contributing factors are folate deficiency, iron deficiency, ineffective erythropoiesis, erythroid hypoplasia, and hemolysis. Patients with documented nutritional deficiencies should receive folate, iron supplementation, or both. Transfusion therapy with packed RBCs is clearly indicated in patients who are symptomatic from their anemia. Chronic transfusion therapy is frequently required, and the clinician should try to attain a hemoglobin level at which symptoms resolve. Long-term transfusion therapy potentially may lead to the development of iron overload syndrome. Thus serious consideration should be given to early institution of iron chelation therapy. For a handful of patients, transfusion requirements have been reported to be reduced after desferrioxamine or deferasirox therapy. Because an oral effective iron chelator, deferasirox, is now available, therapy should be initiated early in the course of the disease when repeated cell transfusion therapy is required. The remainder of approaches to anemic patients deals with therapeutic interventions designed to avoid or diminish the number of transfusions administered.

Low-dose dexamethasone has been reported to be useful in the treatment of patients with transfusion-dependent PMF. Whether these cases represent steroid responses of autoimmune-induced MF and not classic PMF remains unknown. Low-dose melphalan therapy has been successfully used to reduce the transfusion requirements of a reasonable number of PMF patients. Corticosteroids (e.g., prednisone 1 mg/kg/day taken orally) have also been successfully used for treatment of the hemolytic anemia associated with PMF. A 2-g increase in hemoglobin in 29% of men and 52% of women receiving steroid therapy for PMF-associated hemolytic anemia. Folate should be simultaneously administered to all such patients. Even more encouraging results have been reported with simultaneous administration of busulfan and corticosteroids, with clinical responses lasting 6 to 12 months. After patients have reached a peak response, tapering of prednisone should be initiated to determine an acceptable maintenance dose. The hemolytic process frequently recurs after such tapering. It is important to be aware that the hemolytic anemia in patients with PMF may also be a consequence of a coexisting secondary form of paroxysmal nocturnal hemoglobinuria. Paroxysmal cold hemoglobinuria associated with a Donath-Landsteiner antibody should also be excluded as a cause of hemolytic anemia. Furthermore, patients with PMF who receive multiple transfusions are candidates for developing delayed hemolytic transfusion reactions that

occasionally may be severe and persistent. The direct antiglobulin test result is usually positive in this setting. It is generally believed that additional transfusions in these patients with delayed hemolytic transfusion reactions should be avoided if possible. Other therapeutic options for PMF-associated hemolytic anemia include therapy with intravenous immunoglobulins and recombinant human erythropoietin-α (rHuEPO).

Anemia caused by erythroid cell hypoplasia as well as ineffective erythropoiesis in PMF may respond to anabolic steroids. A number of preparations have been suggested, including testosterone enanthate (600 mg/wk intramuscularly), stanozolol (12 mg/day taken orally), nandrolone (3 mg/kg/week intramuscularly), fluoxymesterone (10 mg taken orally three times daily), and oxymetholone (50 mg taken orally four times daily). A good response, as defined by a decrease or total avoidance of transfusion therapy, occurs in about 50% of patients. A course of 3 to 6 months of androgen therapy is indicated to identify responsive patients, but the development of hepatic dysfunction or virilizing side effects may limit long-term androgen administration. Patients with associated chromosomal abnormalities have been reported to be less likely to respond to androgen therapy. Danazol, a synthetic attenuated androgen, has also been useful in reducing the requirement for RBC transfusion support and correction of thrombocytopenia. Danazol appears to be a potentially effective therapy for PMF, which is mainly characterized by BM failure. Thirty-three patients with PMF who were either transfusion dependent or had hemoglobin levels below 10 g/dL were reported to be treated with an initial dose of 600 mg/day of danazol.[18] Of the 30 evaluable patients, a favorable response was seen in 11 (37%), with 27% having a complete response. The median time to response was 5 months (range, 1-9 months). Variables associated with response were lack of transfusion requirement and higher hemoglobin levels. In eight of 30 patients (27%), a moderate increase of liver enzyme levels was reported. It is unknown whether any of the anabolic steroids preparations are superior to the others or whether they are superior to danazol in improving anemia of PMF.

The experience with the use of rHuEPO in PMF has been recently reviewed by Cervantes and colleagues in a total of 51 patients, documenting that 28 (55%) of these patients responded to rHuEPO treatment, including 16 complete and 12 partial responses. Endogenous serum EPO levels inappropriately low for the degree of anemia is predictive of a favorable response to rHuEPO. Serum EPO levels below 125 U/L were found to be associated with a favorable response to rHuEPO therapy. Responses can be associated with a limited enlargement of the spleen.

The use of darbepoetin, a novel hyperglycosylated erythropoiesis-stimulating protein, has been reported in 20 PMF patients. With an initial weekly dose of 150 μg, increased to 300 μg, when no response was observed after 4 to 8 weeks, eight patients (40%) responded to treatment, including six complete and two partial responses, and five maintained their response after a median follow-up of 12 months (range, 4-22 months). The median time to response was 2 months. Univariate analysis indicated that older age was the only factor associated with a favorable response to treatment (P <.006). None of the patients with elevated serum EPO levels responded. Treatment was usually well tolerated, and patients can be successfully switched from rHuEPO to darbepoetin.

Multiple trials have explored the use of thalidomide in the treatment of anemia in PMF based on the drug's antiangiogenic, immunomodulatory, and antiinflammatory actions. A pooled analysis of five small phase II studies published from 2000 to 2002 have indicated that 29% of patients with moderate to severe anemia experience an increase in hemoglobin or reduction or elimination of blood transfusion requirements with thalidomide therapy at a standard dose of 200 to 800 mg/day. Nevertheless, most of the patients treated with these doses had adverse effects that resulted in an attrition rate of greater than 50% after 3 months. Moreover, increases of WBC numbers or platelet counts were frequently reported to be associated with such serious adverse events as pericardial effusions secondary to myeloid metaplasia. Using a dose-escalation design and starting with a low dose of thalidomide (50 mg/day), 31% of patients with transfusion-dependent anemia were reported to experience a response after treatment. A combination of low-dose thalidomide (50 mg/day) with prednisone has been reported to be a better tolerated regimen and equally or more effective than standard-dose treatment. Although the size of the patient population was limited, with this regimen, 40% of patients with an RBC transfusion requirement became transfusion independent, and 95% of the patients were able to complete the 3-month course of therapy with acceptable toxicity. The median hemoglobin level was reported to increase by 1.8 g/dL after low-dose thalidomide and prednisone therapy. This regimen also had a significant effect on the degree of thrombocytopenia and resulted in a reduction in the degree of splenomegaly in almost 10% of the patients. These responses were frequently maintained after therapy was halted. More recent reports provided further evidence that higher doses of thalidomide were not more effective than lower doses. A prospective phase II B, randomized, double-blind, multicenter trial compared therapy with 200 to 400 mg of thalidomide with placebo and documented that in the thalidomide group, only 10 of 26 patients completed 6 months of treatment and that no difference was observed between the thalidomide and placebo groups as regards improvement of hemoglobin levels or reduction of the number of RBC transfusion required. In addition, experience with thalidomide therapy in a two-stage phase II dose-escalation trial in 44 patients with advanced PMF has been reported. Starting at 200 mg/day and increasing to 800 mg as tolerated, the median tolerated dose was 400 mg for a median duration of 3 months; and 20% of the patients experienced improvement in their degree of anemia (21% became transfusion independent). Recently, a more potent thalidomide analog, lenalidomide, has been evaluated in 68 symptomatic patients with PMF at two institutions. Oral lenalidomide was administered at a dose of 10 mg/day if the platelet count was greater than 100,000/mm^3 or at a dose of 5 mg/day if the platelet count was less than 100,000/mm^3 for 3 to 4 months. The overall response rates were 22% for patients with anemia, 33% for patients with splenomegaly, and 50% for thrombocytopenia. Several patients normalized their hemoglobin levels or became RBC transfusion independent. The most common associated toxicities were grade 3 and 4 neutropenia and thrombocytopenia, which occurred in approximately 30% of patients but resolved with discontinuation of therapy. In several patients with del(5)(q31)-associated PMF or post-PV MF, lenalidomide therapy was associated with reduction of the numbers of cells with a marker chromosome as assayed by FISH and reduction of the JAK2V617F burden. Lenalidomide therapy in combination with prednisone therapy in PMF has been evaluated in a phase 2 trial within the Eastern Cooperative Oncology Group and appears to be modestly active and myelosuppressive.[19] Forty-two MF patients with anemia were treated with lenalidomide at 10 mg/day in combination with a 3-month prednisone taper. Grade 3 and higher myelotoxicity was noted in 88% of patients, and a response rate of 23% by IWG-MRT was obtained (19% clinical improvement in anemia or 10% clinical improvement in spleen size). In a single institution, thalidomide therapy and lenalidomide therapy for PMF was compared by retrospectively analyzing the results of three phase 2 trials performed that included 125 patients at this single center. They concluded that lenalidomide plus prednisone therapy was more effective than single-agent thalidomide or lenalidomide therapy. These results are of limited value because lenalidomide therapy plus prednisone therapy was never compared with that achieved with low-dose thalidomide and prednisone, which is associated with less myelosuppression. In this report, low-dose lenalidomide plus prednisone was not associated with an increased incidence of thrombotic events in the absence of any thromboprophylaxis. Some patients who failed to respond to thalidomide or lost their response to thalidomide did achieve significant responses with lenalidomide therapy. Whether either of these immunomodulatory drugs (IMiDs) is superior to the other is the subject of speculation, which would require a large randomized clinical trial. The mechanism by which these agents achieve these clinical responses also remains larger speculation.

Because IMiDs as a class have shown activity in MF and their use is often undermined by neurotoxicity or myelosuppression, recent

interest in the structurally related but more potent pomalidomide in the treatment of MF-associated anemia has led to the completion of several early phase studies and an ongoing randomized phase 3 study. The first study to evaluate the response of pomalidomide in MF was a phase 2 randomized, double-blind, placebo-controlled adaptive design study with four treatment arms. This study reported an overall response in anemia of 24% (10 patients), and 15 of these patients achieved transfusion independence that was durable at 7.5 months. Pomalidomide at 0.5 mg/day with or without a prednisone taper was found to have better responses in anemia with less toxicity compared with pomalidomide at 2 mg/day with or without prednisone. Grade 3/4 myelosuppression and neurotoxicity were not frequent adverse events. A single-center phase 2 study of low-dose pomalidomide was conducted at Mayo Clinic.[20] A cohort of 58 patients were treated with pomalidomide at 0.5 mg/day. Of the 42 transfusion-dependent JAK2V617F-positive MF patients, 10 had significant responses in anemia with nine patients achieving transfusion independence. Although there were no spleen responses, a 58% response in thrombocytopenia for those with baseline platelets below 100×10^9 cells/L was noted. The anemia response was predicted by peripheral blood basophilia within the first month of therapy and the absence of massive splenomegaly and was restricted to MF patients who were JAK2V617F positive. Pomalidomide was also evaluated in a dose escalation phase 1/2 setting with the purpose of determining if higher doses of pomalidomide were more effective in reversing the anemia associated with MF. Doses of 3 mg/day given for 21 of 28 consecutive days were found to be the maximum tolerated dose, and myelosuppression the dose-limiting toxicity without any added response in anemia. The randomized, placebo-controlled, phase 3 RESUME trial is currently ongoing and will provide a definitive answer to the benefit of this IMiD in the treatment of anemia in MF.

Pressure symptoms caused by splenic enlargement can be treated initially with cytotoxic chemotherapy. Busulfan, melphalan, and hydroxyurea have each been used for this purpose. A significant reduction in spleen size with relief of pressure symptoms occurs in 70% of patients receiving chemotherapy.[3] Responses are unfortunately short lived, lasting a median of only 4.5 months. Only 16% of patients with long-term maintenance therapy enjoy sustained relief of symptoms. Hematologic toxicity often necessitates cessation of therapy. Inhibition of the activated JAK–STAT pathway is an attractive therapeutic target in PMF and during the past 5 years has been the focus of both industry and academia in the development of oral small molecule inhibitors. Ruxolitinib, a selective JAK1 and JAK2 tyrosine kinase inhibitor, has recently been approved for the treatment of patients with PMF; this is the first drug approved by the U.S. Food and Drug Administration (FDA) where the indication for use is intermediate- or high-risk MF. The phase 1/2 study determined the optimal starting dose of 15 mg twice daily and that thrombocytopenia and worsening anemia were dose-limiting toxicities.[21] A dose-dependent suppression of phospho-STAT3 was seen in both WT and mutated JAK2 patients treated with ruxolitinib, demonstrating that the drug does not discriminate between mutated and WT JAK2 in its inhibitory activity. Fifty-two percent of treated patients achieved a greater than 50% reduction in splenomegaly for greater than 12 months that was irrespective of their JAK2 mutational status. The debilitating symptoms associated with MF were dramatically improved, and this was correlated with reduction in inflammatory cytokines believed to be mediated through inhibition of JAK1 signaling. This compound was then evaluated in two randomized phase 3 trials, COMFORT 1 (United States, Canada, and Australia) in which ruxolitinib therapy was compared with a placebo control and COMFORT 2 trial (Europe) in which ruxolitinib therapy was compared with the best available therapy.[22,23] The results of each of these trials are remarkably similar, and each trial was adequately powered. Patients with intermediate-2 or high-risk MF as assessed using the IPSS were eligible regardless of JAK2 mutational status. All patients had platelet counts over 100×10^9/L and had a spleen palpated at least 5 cm below the left costal margin. In COMFORT 1, the primary endpoint of 35% or greater reduction in spleen volume was met at 24 weeks in 41.9% of the ruxolitinib-treated cohort and only 0.7% in the placebo group. This response was maintained 48 weeks or more in 67% of treated patients. Fig. 69-7 shows the percent change in spleen volume from baseline at week 24 for individual patients on both arms of this trial and depicts the contrast of spleen reduction in ruxolitinib-treated patients compared with the majority of patients in the placebo arm who had an increase in spleen volume. There were 13 deaths in the ruxolitinib arm and 24 deaths in the placebo arm, revealing a survival benefit for MF patients treated with ruxolitinib with an HR of 0.50 (CI, 0.25, 0.98; $P = .33$). Although grade 3/4 anemia and thrombocytopenia were frequent in the ruxolitinib arm (45.2% and 12.9%, respectively), discontinuation for these events was extremely rare. The primary endpoint in the COMFORT 2 trial was met at 48 weeks with 28% of patients in the ruxolitinib arm and 0% in the BAT arm achieving at least a 35% reduction in spleen volume. The mean length of palpable spleen decreased by 56% at 48 weeks compared with an increase of 4% in the BAT arm. Sophisticated disease-specific quality of life tools were used to evaluate the effects of ruxolitinib therapy on the systemic symptoms that have been presumed to be a consequence of the increased elaboration of inflammatory cytokines modulated by JAK1 signaling. The effects of ruxolitinib were, however, limited in that reversal of histomorphologic abnormalities, including BM fibrosis or osteosclerosis, significant reduction in the JAK2V617F allele burden, and loss of marker cytogenetic abnormalities indicating that the underlying malignant potential of PMF is not affected by this therapy. In addition, abrupt discontinuation of ruxolitinib therapy was associated with rapid return to baseline levels of splenomegaly and severity of the systemic symptoms that at times can be disabling. More gradual tapering of this agent or the use of a short steroid taper is recommended to avoid this complication. Ruxolitinib is an important new agent for the palliation of symptomatic splenomegaly and the debilitating symptoms seen in patients with PMF. The survival data from the COMFORT 1 trial, although modest, are intriguing and suggest that even if an appreciable impact on abnormal BM histopathology or molecular or cytogenetic responses is not seen with ruxolitinib, suppression of the JAK pathway decreases the risk of death, perhaps simply by improving the overall performance status of an individual. The use of ruxolitinib in patients with platelet counts below 100×10^9/L remains experimental, thereby limiting the number of patients who can be treated with this agent. The need to treat patients who are asymptomatic with limited splenomegaly is not apparent since treatment does not appear to affect the underlying

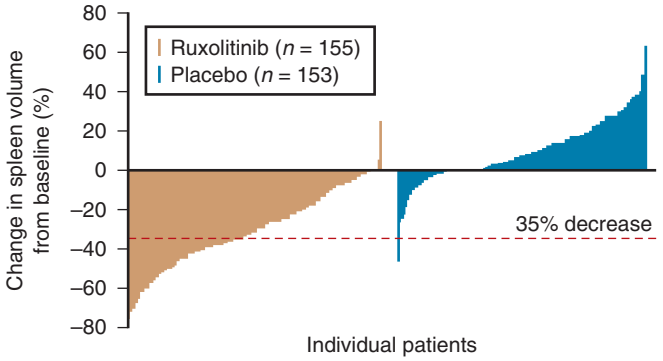

Figure 69-7 REDUCTION IN SPLENIC VOLUME WITH RUXOLITINIB THERAPY IN THE COMFORT 2 TRIAL. The waterfall plot shows the percent change from baseline in spleen volume at week 24 (in 139 patients in the ruxolitinib group and 106 in the placebo group) or at the last evaluation before week 24 (in 16 patients in the ruxolitinib group and 47 in the placebo group). Data for one patient with a missing baseline value are not included on the graph. Most patients in the ruxolitinib group (150 of 155) had a reduction in spleen volume, but most patients in the placebo group had either an increase in spleen volume (102 of 153 patients) or no change (15 of 153 patients). *(Data from Verstovsek S, Mesa RA, Gotlib J, et al: A double-blind, placebo-controlled trial of ruxolitinib for myelofibrosis.* N Engl J Med *366:799, 2012.)*

malignant disorder. A number of other small molecule inhibitors of JAK2 are under various phases of clinical development. These agents have different specificities or toxicity profiles and require evaluation in clinical trials to determine their utility in comparison with ruxolitinib.

Splenic irradiation frequently has been used for treatment of the painful, large spleen syndrome. Irradiation in fractions of 0.15 to 1 Gy administered daily or by an intermittent fractionation schedule (i.e., two or three times a week) to a total dose per treatment course of 2.5 to 6.5 Gy may be effective. Responses are transient, lasting an average of 3.5 months, and hematopoietic toxicity is frequently significant. Splenic irradiation is especially useful for treatment of splenic pain of sudden onset and for treatment of ascites caused by implants of hematopoietic tissue. Radiation therapy should be considered as a temporary measure to be used in patients who are too ill to tolerate splenectomy or chemotherapy. In one series, the median duration of response to irradiation was 6 months, and the median survival after irradiation was 20 months. Splenic irradiation is limited by myelosuppression with significant prolonged cytopenias, which is not predictable and is not correlated with the doses of radiation administered. Splenectomy after irradiation can be associated with increased complications, and irradiation should probably be administered only to patients who are not candidates for surgery.

Radiotherapy offers a viable treatment option and sometimes may be the therapy of choice for the treatment of patients with symptomatic hepatomegaly, peritoneal and pleural implants or pulmonary infiltration leading to ascites or pleural effusions, and EMH in vital organs leading to organ dysfunction. Because of the inherent sensitivity of myeloid tissue to radiation and profound BM suppression that may occur after irradiation, therapy is usually initiated at low doses (20-25 cGy/day), with modification of the dose as the clinical situation dictates. An alternative approach using intraperitoneal administration of cytosine arabinoside has been used to treat ascites in PMF. Therapy is initiated at 0.77 mg/kg/day to achieve a concentration of 30 mg per 2 L of peritoneal fluid. The dosage is advanced so that the patient eventually receives 1 g or 13.5 mg/kg/day. Abdominal pain is the most common adverse effect associated with this approach. Low-dose, single-fraction, whole-lung radiotherapy has also been useful in treating pulmonary artery hypertension associated with PMF.

Splenectomy remains a viable option even in the face of the recent availability of JAK2 inhibitors in patients with hemolysis, thrombocytopenia, painful splenomegaly, recurrent splenic infarction, and portal hypertension refractory to other therapeutic modalities or in individuals with leukopenia or thrombocytopenia that prevents one from resorting to therapy with chemotherapeutic agents or a JAK2 inhibitor. Splenectomy in patients with PMF is associated with a postoperative morbidity rate of 15% to 30% and a mortality rate of almost 10%. These events largely result from episodes of bleeding, infection, and thrombosis.[24] After splenectomy, 77%, 50%, 40%, and 30% of patients, respectively, have been reported to experience long-term improvement in symptomatic splenomegaly, anemia, portal hypertension, and severe thrombocytopenia. Bleeding and thrombotic complications, however, complicate the course of 25% of patients with PMF, and 6.7% of patients die during the perioperative period. Postoperatively, the major long-term complications include leukocytosis, thrombocytosis, and accelerated hepatic enlargement. Such adverse events can frequently be controlled with the immediate institution of hydroxyurea therapy during the postoperative period or if treatment with 2-chlorodeoxyadenosine therapy is unsuccessful. The appropriate implementation of splenectomy can result in the improved quality of life of PMF patients who frequently do not have other therapeutic options available. Because splenectomy is associated with significant morbidity and mortality, the physician should only resort to this strategy if thrombocytopenia, anemia, or symptomatic splenomegaly is unresponsive to less invasive approaches. Patients should only be considered for this procedure if their performance status allows one to anticipate a favorable surgical outcome with some certainty. Excessive delay of the decision to undergo splenectomy may result in a missed window of opportunity because the patient may become increasingly debilitated, no longer making him or her a viable surgical candidate. Histopathologic and cytogenetic features of the patient's BM did not predict the likelihood of response for the cytopenias to splenectomy. Progressive hepatomegaly and marked thrombocytosis occurred, respectively, in 16% and 22% of patients after splenectomy. The latter was associated with increased risk of thrombosis and decreased postoperative survival duration. An extraordinarily high rate of leukemic transformation has been observed after splenectomy. Whether this was a function of the absence of the spleen or more likely the consequence of the natural history of the disease is unknown. It has been suggested that splenectomy is an independent risk factor for leukemic transformation, stemming from a disruption of the host–tumor relationship, but others argue that patients with late-stage PMF who required splenectomy might be undergoing leukemic transformation in areas of splenic EMH without overt BM transformation. This population may be destined to develop leukemic transformation, and the need for splenectomy may only serve to identify this group of patients before such an event. 2-Chlorodeoxyadenosine therapy can be a particularly useful agent for patients with increased hepatomegaly, rapidly rising white blast cell counts, an extreme degree of thrombocytosis after splenectomy or for patients with these same clinical features who have not undergone splenectomy. The drug can be administered every 4 weeks according to one of two dosing schedules (0.1 mg/kg/day intravenously by continuous infusion for 7 days, or 5 mg/m^2/day for 2 hours intravenously for 5 consecutive days). Responses occur usually by the second cycle, and the medium duration of response is 6 months. 2-Chlorodeoxyadenosine can be extremely useful in controlling the excessive myeloproliferation in patients awaiting an allogeneic stem cell transplant.

Excessive bleeding in patients with PMF can be a result of thrombocytopenia, qualitative platelet defects, or DIC. Based on clinical observations, it is recommended that splenectomy be avoided in patients with DIC. Actively bleeding patients with consumption coagulopathy should receive platelet and plasma replacement therapy. Low-dose heparinization has resulted in improvement in some patients.[3] Platelet transfusions are suggested in bleeding patients who are thrombocytopenic or have normal platelet counts but who are known to have qualitative platelet abnormalities. Factor VII infusions should be considered in patients with bleeding refractory to platelet transfusion.

Allogeneic SCT is a potentially curative option in patients with PMF who have an appropriate donor available. Successful transplantation is associated with gradual resolution of BM fibrosis and normalization of hematopoiesis (see box on Algorithm for Selection of Appropriate Patients for Stem Cell Transplantation Stratified According to Risk Status).

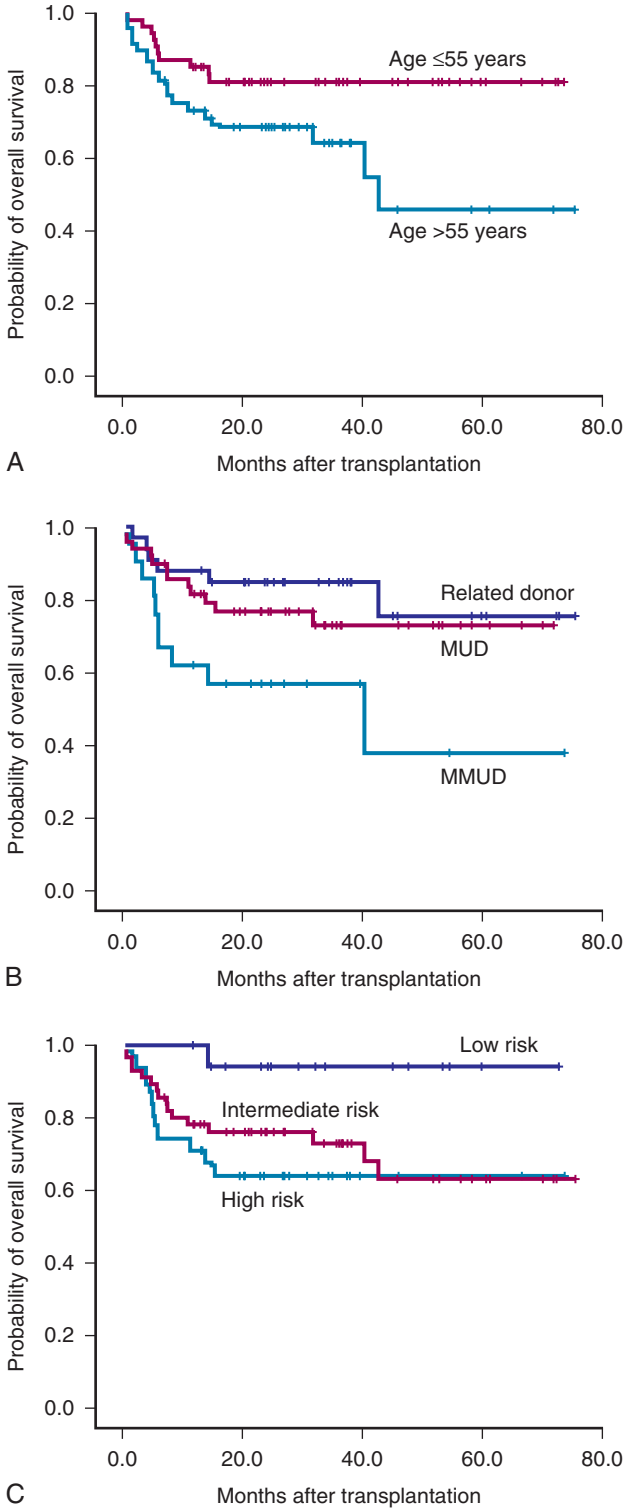
Most of the knowledge of allogeneic SCT with conventional conditioning regimens comes from two series of transplants with more than 50 patients each. In the two cohorts of 55 and 56 PMF patients, the median age of transplanted patients was 42 and 43 years; treatment-related mortality (TRM) was 27% and 33%; and 5-year survival was 47% and 58%, respectively. The 5-year probability of treatment failure caused by relapse or persistent disease after transplantation was 36%, and the failure of sustained engraftment was 10.7% and occurred solely in patients receiving transplants from alternative donors. A hemoglobin level of 10 g/dL or less and osteomyelosclerosis before transplantation adversely affected the outcome. The probability of grade III or IV acute graft-versus-host disease (GVHD) was 33%, with 16 of 45 patients developing extensive chronic GVHD. Multivariate analyses demonstrated the influence of age on 5-year survival (14% for patients 45 years or older compared with 62% for those younger than 45 years). In an update from the Seattle group, the experience with 95 PMF patients who received busulfan, a total-body irradiation conditioning reagent, was provided. The 7-year actual survival rate was 61%, although 10% of patients died of recurrent or a persistent disease and the non–relapse-related mortality at 5 years was 34%. An even higher 1-year cumulative nonrelapse mortality of 48% was reported from two Canadian centers in 25 patients. These reports of myeloablative allo-HSCT in PMF provide evidence that engraftment can be achieved and that a

complete and durable remission of the disease can occur in approximately 50% of patients. However, owing to the poor transplant outcomes in older patients, enrollment to this procedure represents a major therapeutic dilemma in PMF patients who are primarily diagnosed at ages in excess of 60 years.

The advent of nonmyeloablative, reduced-intensity conditioning (RIC) regimens for allogeneic SCT has expanded the use of the procedure to older patients. As a result of diminished transplantation-related toxicity, it has been possible to investigate the usefulness of allo-SCT in patients with PMF previously believed to be unsuitable candidates because of advanced age. The use of RIC regimens in older patients with PMF has resulted in lower TRM and achievement of histohematologic responses.

Rondelli and coworkers reported retrospectively the outcome of 21 PMF patients with a median age of 54 years and a range from 27 to 68 years who were transplanted at various centers using RIC regimens. All patients had an intermediate or high disease, taking into account hemoglobin and WBC count values. However, no patient had undergone leukemic transformation. Different conditioning regimens, most of which contained fludarabine, resulted in a TRM of 10% and 2-year overall survival rates of 87%. Eighteen patients were alive 12 to 122 months (median, 31 months) after transplant, and 17 were in remission (1 after a second transplant), with a relapse rate of 14%. Thirty-three percent of the patients developed acute GVHD grades II to IV, and 72% developed chronic GVHD. Posttransplant chimerism analysis showed more than 95% donor cells in 18 patients, and two patients achieved complete donor chimerism after donor lymphocyte infusion (DLI). The European Group for Blood and BM Transplantation has performed a prospective study of RIC conditioning for allogeneic SCT.[25] This study was performed at multiple sites and included 103 patients who received a RIC conditioning regimen of busulfan and fludarabine followed by an allogeneic stem cell graft from related (n = 33) or unrelated donors (n = 70). The estimated 5-year event-free survival and overall survival was 51% and 67%, respectively . As can be seen in Fig. 69-8, human leukocyte antigen (HLA) mismatching and advanced disease remain poor prognostic parameters, but even in this high-risk group, the overall survival was approximately 40%. Of course, older patients had a less favorable outcome than younger patients, but individuals older than 55 years of age have an overall survival of 48%. Remarkably, patients younger than 55 years of age had a 5-year overall survival rate of 82%. Elimination of JAK2V617F after transplant was associated with a reduced incidence of relapse. The Seattle group has reported their single-center experience that included 100 patients using modern conditioning regimens and reported a day 100 mortality rate of 13%, a relapse rate of 11%, and a 7-year actuarial survival of 61% for HLA-matched related and unrelated transplants. In a retrospective study of allogeneic SCT of 30 PMF patients between the ages of 60 and 78 years transplanted at four different centers, 3-year overall survival and progression-free survival rates of 45% and 40% were reported, respectively. One of the limitations of widely applying allogeneic SCT to more patients with PMF is the lack of access to appropriate donors. Recently, Takagi and coworkers from Japan reported surprisingly positive results with cord blood grafts for RIC allogeneic transplantation in adults (median age, 57.5 years) with various hematologic disorders associated with extensive BM fibrosis (PMF, post-MPN AML, and MDS-related AML). The estimated probability of survival at 4 years for this group was 28.6%, which is modest but considerably superior to that which would be anticipated with presently available chemotherapy regimens for such high-risk disease. This study provides the rationale for the further evaluation of RIC allogeneic transplant for eligible PMF patients lacking an HLA-matched sibling or unrelated donor with the use of alternative sources of grafts such as cord blood units or possibly haploidentical donors. Occasionally, patients with PMF after allogeneic transplant can experience relapse of their underlying disease, failure of engraftment, or graft failure. Relapse can frequently be treated with donor lymphocyte infusions. Second RIC allogeneic transplants should be considered for individuals who do not respond to donor lymphocyte infusions or experience difficulty with engraftment or late graft failure.

The feasibility of viewing allogeneic SCT as the preferable therapeutic option for intermediate- and high-risk PMF continues to be an area of great debate. Not all patients are candidates for allogeneic transplantation because of comorbidities or a poor performance status because of the systemic effects of the underlying PMF. Although the JAK2 inhibitors are largely palliative, they do reduce the degree of splenomegaly and often improve the performance status of such



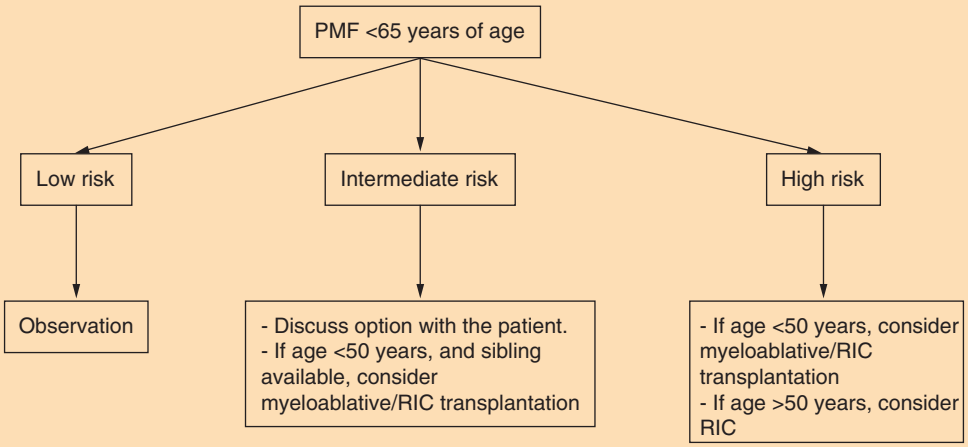


Figure 69-8 Survival of patients with myelofibrosis after reduced-intensity allogeneic stem cell transplantation according to age **(A),** donor **(B),** and Lille risk profile **(C).**

Algorithm for Selection of Appropriate Patients for Stem Cell Transplantation Stratified According to Risk Status

patients, frequently resulting in weight gain, and improve their candidacy for transplant. The reported outcomes with JAK2 inhibitor therapy, albeit limited in regard to overall survival, might actually increase the number of patients who will ultimately be eligible for transplant because of the improvements in performance status. This approach is currently being evaluated within the MPD-RC.

The fact that allogeneic RIC transplant is curative in appropriate patients is undeniable, and the improvements in the design of conditioning regimens and supportive therapy make this a viable first-line approach for individuals with HLA-matched donors and advanced disease. Whether such an approach should also be implemented in patients with earlier phases of the disease is a point of contention that requires further careful investigation. This decision is especially important in young patients with early forms of PMF because their disease is likely to eventually progress, and the best results with allogeneic transplant have been reported in such low-risk patients. The flaw in the argument to proceed with immediate transplant in young patients with early PMF is the exposure to significant mortality and morbidity in a patient population that frequently can anticipate a decade or more of a good quality life with no or minimal therapeutic interventions. Although longer term follow-up data and larger studies are desirable, nonmyeloablative transplantation appears to be a promising therapeutic option in older patients with PMF before leukemic transformation.

Many unresolved issues remain to be clarified concerning the optimal strategy for allo-SCT in PMF. The need for splenectomy before allo-SCT remains a major issue. Splenectomy before allo-HSCT in PMF results in faster hematopoietic recovery. The role of splenectomy before HSCT should be evaluated in prospective studies. Our initial observations in patients who were prepared with fludarabine and melphalan and then received an allogeneic HSCT suggest that even extensive splenomegaly (>30 cm longitudinal size by computed tomography scan) does not prolong hematologic reconstitution after transplant, thereby avoiding delays of going to transplant caused by prolonged postoperative recovery times after splenectomy.[26]

The establishment of valid complete remission criteria of PMF after allogeneic SCT remains a major issue because the conventional criteria for response after allo-SCT are often influenced by GVHD, infections, or poor graft function and cannot be used. Conversely, normal blood counts and disappearance of disease-related symptoms do not exclude residual disease. Molecular markers of minimal residual disease monitoring have been evaluated as a biomarker for long-term disease-free survival. A highly sensitive method to monitor and quantify V617F-positive cells in mutation-positive patients with PMF after SCT allowed detecting minimal residual disease. This method has proven useful as a parameter for complete remission assessment and as a guide for instituting adoptive immunotherapy.

Autologous transplantation has also been investigated based on the premise that BM fibrosis and EMH are related to the bulk of the neoplastic clone and therefore successful debulking using high-dose chemotherapy may interrupt the disease process and improve the disease manifestations at least until the reestablishment of the abnormal clone in the BM by the "contaminated" autologous graft is achieved. This hypothesis was tested in a study in 21 patients with PMF. The median patient age was 59 years. The conditioning regimen consisted of oral busulfan (16 mg/kg). The median times to neutrophil and platelet recovery were 21 days and 21 days, respectively. Five patients required backup stem cell infusions because of delayed engraftment. The 2-year actuarial survival rate was 61%. Six patients died of non–relapse-related causes ($n = 3$) or disease progression ($n = 3$). Transfusion independence was achieved in 10 of 17 anemic patients and four patients with platelet counts of less than 100×10^9/L responded with durable counts of more than 100×10^9/L. Although this study clearly demonstrates the feasibility of this procedure, the role of autologous transplantation in PMF remains uncertain.

With increased understanding of the biology of PMF, a number of phase I and II studies have examined more rational therapy for PMF. NFκB has been shown to be upregulated in megakaryocytes and $CD34^+$ HSC in patients with PMF and is believed to contribute to the elaboration of TGF-β from megakaryocytes and monocytes. In a TPO^{high} murine model, deregulation of MPL signaling results in a phenotype that mimics PMF. Treatment of these mice with bortezomib resulted in decreased expression of TGF-β1 and osteoprotegerin with improvement in myeloproliferation and reduction in retuclin fibrosis and osteosclerosis. Bortezomib, a proteosome inhibitor with the ability to downregulate NFκB, appears to be an effective strategy in MF. A multicenter pilot phase 2 study of nine MF patients treated with bortezomib was conducted. Seven of the patients experienced at least grade 3 toxicity of which the majority were nonhematologic. No appreciable clinical responses were seen in this study. The MPD-RC also conducted a phase I/II trial of single-agent bortezomib in 12 MF patients in the phase I portion of the study and found the MTD to be 1.3 mg/m^2 given on days 1, 4, 8, and 11 of a 28-day cycle with a dose-limiting toxicity of thrombocytopenia. There were no cases of clinical improvement in the 16 evaluable phase 2 MF patients, and there was no statistically significant reduction in TGF-β from baseline. Interestingly, although bortezomib did not reduce VEGF levels from baseline, it did induce significant reduction in median vessel density within the BM and exerted a detrimental effect of downregulating CXCR4 expression in $CD34^+$ MF cells.

The identification of various epigenetic defects in PMF has also provided novel therapeutic targets, and preclinical studies are actively being translated into early phase clinical trials. Shi et al presented data

suggesting that chromatin-modifying agents such as DNA methyltransferase inhibitors and histone deacetylase inhibitors might be candidate agents for the treatment of PMF.[27] Inoue et al have reported the successful treatment of a single patient with PMF with severe anemia and thrombocytopenia with the histone deacetylase inhibitor valproic acid. This class of agents leads to accumulation of acetylated histones, which in turn leads to increased tumor suppressor gene expression. The DNA methyltransferase inhibitor 5-azacitidine has been evaluated in a phase 2 study in 34 MF patients.[28] The overall response rate was 24% after a median of 5 months of treatment, and grade 3/4 myelosuppression was seen in 29% of patients, requiring dose reduction in 47% of the cases. Interestingly, there was no difference in global hypomethylation between responders and nonresponders. This finding could argue that the mechanism of action of this drug in responding MF patients may not be directly through induction of DNA promoter site demethylation. Studies designed to evaluate the methylation status of specific genes thought to be silenced by this epigenetic modification (e.g., $p15^{INK4b}$ and p16INK4a) need to be done in the future. A modified 5-day course of 5-azacitidine was also tested in a group of 10 MF patients and was found to have even less response rate than the full 7-day course. Case series highlight the potential role of decitabine in the treatment of MF in blast phase, and initial reports of subcutaneous low-dose decitabine in advanced MF also appears to hold promise and is currently being evaluated in larger studies. LBH589 (panobinostat) is a potent pan-deacetylase inhibitor that has also been evaluated in PMF patients in two separate trials with thrombocytopenia as the dose-limiting toxicity and the demonstration of a signal of clinical activity that is associated with enhanced histone acetylation. A report of the results of long-term administration of low-dose panobinostat in MF patients demonstrated the potential to alleviate constitutional symptoms, reduce splenomegaly, improve anemia, eliminate peripheral blood leukoerythroblastosis, reduce BM reticulin and collagen fibrosis, and restore normal BM morphology in a small number of patients. A phase II study of panobinostat at a dose of 25 mg orally TIW weekly is currently ongoing, and studies combining this agent with ruxolitinib are ongoing, and the results are highly anticipated. The therapeutic potential for the use of chromatin-modifying agents for the treatment of PMF patients is an exciting approach and requires further careful evaluation in well-designed clinical studies.

FUTURE DIRECTIONS

More rational therapies for PMF should evolve from further enhancement of the understanding of the cellular and molecular biologic abnormalities underlying PMF. Studies defining the relative contributions of acquired genetic mutations, epigenetic events, as well as the influence of the BM and splenic microenvironment on the origins of PMF, disease progression, and events leading to leukemic transformation are required. Because PMF originates at the level of the HSC, the identification of novel drugs that eliminate such malignant stem cells is likely the most direct route to potentially curative pharmacologic strategies. Also, further delineation of the therapeutic potential of INF as well as histone deacetylase inhibitor therapies must be pursued to define their potential use in the management of PMF patients. The evaluation of the use of combinations of active agents, including the JAK2 inhibitors, IMiDS, histone deacetylase inhibitors, and pegylated forms of INF are anticipated to lead to significant clinical improvements in the outcomes of PMF patients. The evaluation of these combination therapies will certainly require the use of novel strategies for the design of clinical trials that will evaluate the effects of several active agents used either simultaneously or sequentially. Overall, the implementation of any therapeutic approach by the practicing community of hematologists should require evidence that can be gained only by the completion of well-planned and adequately powered phase 3 trials comparing the experimental approach to the standard of care. Allogeneic SCT with RIC and peripheral blood stem cell grafts remains the only potentially curative therapy available for patients younger than 65 years of age with an acceptable performance status. Although there is a reluctance to expose PMF patients to the risks of allogeneic SCT, if their underlying disorder is associated with a poor prognosis, this risk appears to be warranted. Because early forms of PMF are associated with survival of well over a decade, many individuals have been even more reluctant to expose such patients to experimental therapeutic agents or allogeneic transplant. Unfortunately, progression to more advanced forms of MF is anticipated in younger patients. Exploration of therapeutic agents that can delay or even prevent disease progression or identification of the appropriate role of allogeneic stem cell transplantation in this low-risk group will require additional study. The decision to proceed to transplant requires a detailed discussion of the risks and benefits of such a high-risk but potentially curative procedure. The establishment of multi-institutional cooperative groups to evaluate such novel therapies and treatment strategies for PMF patients remains a continuing critical need. No single institution has sufficient numbers of patients to perform this ever-growing number of required investigative efforts. Only with the completion of such rigorous evaluations of individual therapeutic strategies will one be able to determine the value of a continuously growing number of potentially active agents used alone or in combination. Each new therapy will likely be evaluated using not only a number of clinical endpoints but also surrogate biomarkers and consideration of the immediate and long-term toxicities associated with their use documented. The European Myelofibrosis Network and the IWG for Myelofibrosis Research and Treatment have independently developed objective criteria by which responses to experimental therapeutic agents can be judged.[29,30] Furthermore, quality of life tools have become more widely used in the evaluation of such experimental therapeutic agents. The presently available instruments used for this purpose are clearly imperfect and will require modification to be more effective in evaluating the impact of a particular treatment strategy. Because it is likely that a large

Case Vignettes

How should PMF patients with thrombocytopenia be treated?

Platelet count 50 to 100 × 10^9/L:

It is important to ensure that vitamin B_{12} or folate deficiency is not contributing to the low platelet count as well as suppression from prior chemotherapeutic agents. Chemotherapeutic agents such as hydroxyurea can be used in patients with marked splenomegaly because initially this can result in an improvement in platelet count as the spleen is reduced in volume. Patients can also be treated with thalidomide or lenalidomide in combination with prednisone. These first-generation IMiDs can sometimes improve cytopenias and reduce splenomegaly in PMF patients, and in some cases, this response can persist even after drug discontinuation. Lenalidomide can induce cytopenias to a greater extent than thalidomide, and this needs to be taken into consideration before the use of this agent in this setting. In a phase II trial, pomalidomide was reported to have a response rate of 58% in increasing the baseline platelet count by greater than 50% in patients with baseline platelets above 50 × 10^9/L. This second-generation IMiD will need to be evaluated in patients with platelet counts below 50 × 10^9/L. The use of JAK2 inhibitors in patients with reduced platelets counts remains a subject of research because these agents are associated with thrombocytopenia. For patients with symptoms related to splenomegaly and constitutional symptoms, a recently FDA-approved JAK1/2 inhibitor, ruxolitinib, is being evaluated in a clinical trial in MF patients with this platelet

Case Vignettes—cont'd

range. Patients can also be enrolled in other JAK2 inhibitor clinical trials in which reduced platelet counts are acceptable or in clinical trials with other agents in development. If thrombocytopenia worsens with the current treatment plan, then proceed with the strategy outlined below.

Platelet count 20 to 50 × 10^9/L:

Thalidomide or lenalidomide in combination with prednisone can be attempted to correct anemia in these PMF patients but rarely improve the platelet count in a clinically meaningful way. Most clinical trials involving a variety of therapeutic agents including JAK2 inhibitors will require baseline platelets above 50 × 10^9/L. In patients who are experiencing life-threatening bleeding, in addition to aggressive immediate platelet transfusions, splenectomy is a reasonable therapeutic option.

Platelet count below 20 × 10^9/L

The treatment choices are truly limited for these patients. Intervention is also dependent on the clinical picture with emphasis on addressing bleeding. Supportive therapy with frequent platelet transfusions is a possibility, but it is likely not sustainable in the long term. It is our practice to transfuse if platelets are below 10 × 10^9/L unless there is no evidence of mucosal bleeding or life-threatening hemorrhage. Occasionally, patients may have an improvement in the degree of thrombocytopenia with steroids; however, this has not been systematically evaluated. About 20% to 30% of patients with severe thrombocytopenia will have significant improvement in platelet counts after a splenectomy. Aggressive platelet transfusional support is necessary before, during, and after splenectomy in many cases. However, splenectomy in patients with PMF is associated with a postoperative morbidity rate of 15% to 30% and mortality rate of close to 10%. These numbers, however, are highly dependent on the institutional experience and the operating surgeon. Splenectomy can also result in EMH in the liver, causing hepatomegaly, which may require the administration of judicious amount of chemotherapeutic agents (hydroxyurea, busulfan, cladribine). Severe thrombocytopenia is an adverse prognostic feature. Such patients who are eligible for stem cell transplant and have available donors should be considered for transplantation. TPO mimetics have been associated with increased BM fibrosis when used for the treatment of ITP and have not been evaluated in the setting of PMF-associated thrombocytopenia. Additionally, patients with extreme thrombocytopenia and signs of leukemic transformation can be considered for therapy with decitabine or azacytidine with aggressive platelet transfusional support and then should proceed on to allogeneic SCT if a donor is available and the patient's performance status is appropriate.

Which patients should be considered for allogeneic stem cell transplantation?

Allogeneic SCT is the only potential curative treatment option for PMF. Patients with poor risk features and decreased probability for survival should be considered for SCT because of the not insignificant risk of transplant related morbidity and mortality. All patients younger than 70 years of age and their siblings should be HLA typed at the time of diagnosis to determine if there is a potential match. Patients between the ages of 65 and 70 years with available related donors should be evaluated based on their performance status and comorbid conditions. Patients younger than 65 years with good performance status and available donors (either related or fully matched unrelated) should be encouraged to undergo evaluation for SCT soon after the diagnosis and preferably within a clinical trial. Patients with high- or intermediate-risk disease with available donors should consider transplantation before developing debilitating symptoms or significant worsening in their performance status. Patients with low-risk disease should be closely monitored without intervention but should proceed to transplantation with evidence of disease progression. For patients with available donors but poor performance status because of symptoms of MF, a course of treatment with ruxolitinib can be considered with a goal of improvement in performance status associated with reduction of splenomegaly and constitutional symptoms. These patients may become more viable transplant candidates with this pretransplant treatment approach. Splenectomy before transplant is not essential to ensure adequate engraftment. Currently, SCT using RCI regimens, haploidentical donors, and cord blood grafts are being evaluated.

Which PMF patients are appropriate for JAK2 inhibitor therapy???

Not all patients require treatment with JAK2 inhibitor therapy. Patients with symptomatic splenomegaly or debilitating MF-related symptoms are potential candidates for treatment with ruxolitinib. Inhibition of JAK1/2 is associated with myelosuppression and could further compromise existing cytopenias. In patients with splenomegaly and constitutional symptoms with adequate blood counts, a course of hydroxyurea should be considered. If the patient fails hydroxyurea or has debilitating symptoms, then ruxolitinib would be the appropriate agent. Ruxolitinib is currently approved for patients with intermediate- and high-risk MF and has yet to be explored in cases of symptomatic patients with low-risk disease. Additionally, this drug has not yet been fully evaluated in MF patients with platelet counts below 100 × 10^9/L. Ruxolitinib could also be used in patients with poor performance status before allogeneic SCT as a means to improve their performance status and promote weight gain in an attempt to optimize them for SCT. Although the COMFORT 1 trial reported a modest improvement in survival at a median of 51 weeks of treatment with ruxolitinib, the exact mechanism that would provide for this survival benefit is not yet understood, and this agent should not be given with the primary goal of disease process modification and increased survival. Patients started on ruxolitinib need to have frequent monitoring of blood counts, and if discontinued, the dose should be either tapered or a pulse of steroid therapy considered to avoid the rapid reappearance of systemic symptoms and splenomegaly.

number of such agents will be evaluated in patients with PMF in the future, it is recommended that a uniform standard be adopted so that the relative efficacy of any new therapeutic approach can be more easily judged. The integration of these new classes of agents can also be incorporated into the conditioning regimens that are used before allogeneic SCT; this approach will also likely contribute to significant improvements in outcomes in PMF patients undergoing allogeneic stem cell transplant.

CHAPTER 70

EOSINOPHILIA, EOSINOPHIL-ASSOCIATED DISEASES, CHRONIC EOSINOPHIL LEUKEMIA, AND THE HYPEREOSINOPHILIC SYNDROMES

Marina Kremyanskaya, Steven J. Ackerman, Joseph H. Butterfield, John Mascarenhas, and Ronald Hoffman

Since the initial identification of the eosinophilic granulocyte (Fig. 70-1) by Paul Ehrlich in 1879, an extensive number of diseases and conditions characterized by blood and/or tissue eosinophilia (Table 70-1) have been identified. Researchers have also gained a better understanding of the unique cellular characteristics of activated tissue and peripheral blood eosinophils; their preformed granule protein constituents and inducible lipid, oxidative, and cytokine products; and the eosinophil's proinflammatory and cytotoxic potential in the pathogenesis of allergic, parasitic, neoplastic, and a variety of other idiopathic disease processes. Recognition of the eosinophil as a proinflammatory effector cell has fueled a surge of interest in this granulocyte's role in a growing number of disorders.

Studies of the biochemistry, biologic activities, and in particular, the localization in tissues of the distinctive enzymatic and nonenzymatic cationic protein constituents of the eosinophil's secondary or specific granules have provided convincing evidence for its role in the pathogenesis of inflammation and tissue damage in eosinophil-associated diseases. In addition, identification of specific granule constituents in tissues has supplied additional evidence for the participation of eosinophils in diseases not normally associated with tissue or blood eosinophilia. Investigations of the biochemistry, functions, and localization in tissues of these unique enzymatic and nonenzymatic cationic proteins have now provided compelling evidence supporting a pathologic effector role for the eosinophil in directly inducing tissue damage. These five distinctive cationic granule protein constituents include the two major basic proteins (MBP-1, MBP-2), eosinophil peroxidase (EPX), and the two ribonucleases eosinophil cationic protein (ECP) and eosinophil-derived neurotoxin (EDN). Eosinophils also have the capacity to express toxic oxidative intermediates, eicosanoid and other lipid mediators of inflammation, and cytokines that are integral to their normal and pathologic role in disease. This chapter provides an overview of current knowledge and understanding of eosinophil biology, focusing principally on clinical disorders associated with hypereosinophilia—in particular, hypereosinophilic syndrome (HES).

Eosinophilia is defined as the presence of greater than 450 to 500 eosinophils/microliter of blood as normally measured by sampling peripheral blood.[1] The process of determining the cause of eosinophilia is often a frustrating experience for both physician and patient, one that may still result in a significant number of patients being classified as having hypereosinophilia of unknown etiology. HES is a group of disorders marked by sustained overproduction of eosinophils and tissue infiltration. In addition to the striking and sometimes profound eosinophilia associated with the syndrome, HES is characterized by a predilection for end-organ damage most commonly involving the heart, with the development of eosinophilic endomyocardial fibrosis and related cardiac pathologies. Heart disease can, however, also develop with eosinophilias due to other causes, for example, tropical eosinophilia and certain cancers. The initial defined criteria for HES were originally provided by Chusid and colleagues and served to distinguish HES patients from those with identifiable (reactive) causes of eosinophilia. Of interest, the more recent identification of subgroups of patients who have profound idiopathic eosinophilia (IE) characteristic of HES but do not go on to develop end-organ damage characteristic of HES (e.g., patients with episodic angioedema with eosinophilia) complicates the diagnosis, treatment, and management of patients with profound eosinophilia of unknown etiology. HES remains a useful term, but with increasing understanding of the variants of the syndrome, it is likely more accurate to use the term as a diagnostic feature rather than to define a primary hematologic disease. Myeloproliferative neoplasm (MPN) associated with eosinophilia can occur in patients who may or may not present with organ damage. Furthermore, 10% to 15% of patients with HES have been shown not to have a myeloid malignancy; rather, their eosinophilia is driven by an abnormal clonal $CD3^{-}CD4^{+}$ T-cell population producing interleukin-5 (IL-5). This variant is referred to as *lymphocytic variant hypereosinophilia*. Furthermore, a small number of patients with a clinical picture of HES have been shown to have myeloid malignancies associated with fusion proteins involving platelet-derived growth factor receptor (PDGFRA or PDGFRB) or the fibroblast growth factor receptor (FGFR). These disorders are categorized by the World Health Organization (WHO) as myeloid and lymphoid malignancies associated with eosinophilia and genetic abnormalities. Chronic eosinophilic leukemia (CEL) is considered an MPN and is referred to as *CEL not otherwise specified (CEL-NOS)*. These patients have peripheral blood eosinophilia (>30%), lack mutations in PDGFR, KIT, or FGFR, and have less than 20% blasts or features of acute myeloid leukemia, including inversion of chromosome 16, but they have other cytogenetic or molecular markers indicative of clonal hematologic malignancies and a blast cell count greater than 2% in the peripheral blood and 5% in the bone marrow. Acute eosinophilic leukemia (AEL), by contrast, is a variant of acute myeloid leukemia (AML) characterized by greater than 30% of nucleated marrow cells being eosinophils and greater than 20% being myeloblasts. The wide variety of these categories indicates the heterogeneity of what was previously termed *HES* and emphasizes the importance of incorporating histomorphologic criteria, as well as molecular and genetic criteria, when evaluating such patients. Those patients in whom reactive and clonal eosinophilia have been excluded are classified as having idiopathic eosinophilia. Some of these IE patients have end-organ damage associated with eosinophilia and suffer from the clinical syndrome of HES.

EPIDEMIOLOGY

No population-based data are available to indicate the incidence or prevalence of the heterogeneous syndromes referred to as *HES.* An attempt to estimate these data has been made by using the Surveillance, Epidemiology and End Results (SEER) database sponsored by the National Cancer Institute. A crude incidence of 0.035 cases per 100,000 person years was obtained, and the male-to-female ratio was 1.47. The average age at diagnosis was 52.5 years, and the peak incidence was in individuals 65 to 74 years of age. Infrequent cases

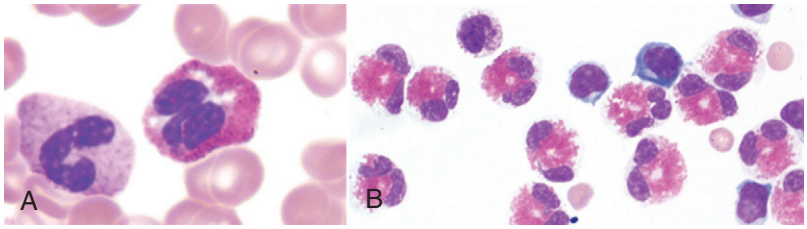

Figure 70-1 EOSINOPHIL AND EOSINOPHILIA. **A,** Eosinophil in a standard peripheral blood smear *(center)* compared with a neutrophilic granulocyte *(left).* The eosinophil usually has a bilobed nucleus and heavily condensed chromatin usually with two lobes. The granules are considerably larger than those of a neutrophil and are spherical *red-orange* and refractile. They fill the cytoplasm and frequently overlie the nucleus. **B,** An eosinophilia is illustrated in a CSF specimen from a patient with hydrocephalus and a V-P shunt; apparently the eosinophilia is due to an allergic response.

have been described in infants and children.[2] These data have serious limitations and emphasize the need for more comprehensive epidemiologic data using currently available diagnostic criteria. Of interest, the overwhelming number of patients with FIP1L1-PDGFRA variants of hypereosinophilia are males.

PATHOPHYSIOLOGY

Eosinophil Morphology

Eosinophils contain three distinct membrane-bound granule populations that are produced during their differentiation from hematopoietic progenitor cells (Fig. 70-2). These include (a) round, uniformly electron-dense primary granules, present mainly at the eosinophilic promyelocyte/myelocyte stages; (b) specific or secondary granules, containing an electron-dense crystalloid core surrounded by a less dense granular matrix (>95% of granules in mature eosinophils and the morphologic hallmark of this granulocyte); and (c) less well-characterized small granules, which may contain catalase and may be functionally analogous to lysosomes and peroxisomes of other cells and which serve as sites for hydrolytic enzymes such as acid phosphatase and arylsulfatase.[3] The large, specific granule is the major repository for the eosinophil's cytotoxic and proinflammatory cationic proteins, which also confer its tinctorial (eosinophilic) properties. Eosinophils also contain lipid bodies, non–membrane-bound lipid-rich organelles often confused with granules, and present in many types of leukocytes and other cells. Normal eosinophils contain greater numbers of lipid bodies than neutrophils, and the numbers of lipid bodies increase during eosinophil activation in vitro and engagement in inflammatory reactions in vivo. Although the functions of lipid bodies are incompletely understood, they incorporate fatty acids such as arachidonate and likely serve as intracellular depots for its storage and metabolism, as suggested by the lipid body localization of all the principal eosinophil eicosanoide-forming enzymes, including 5-lipoxygenase, leukotriene C4 synthase, and cyclooxygenase. These four organelles, along with vesiculotubular structures and small vesicles involved in transport and secretion in the activated cell, serve as the major subcellular sites for the eosinophil's armamentarium of preformed cytotoxic and inflammatory mediators.

EOSINOPHIL DEVELOPMENT, RECRUITMENT, AND ACTIVATION

Eosinophilopoiesis

Eosinophils are derived from marrow $CD34^+$ cells in response to a number of T cell–derived eosinophilopoietic cytokines and growth factors, including IL-3, GM-CSF, and IL-5. Although eosinophils and basophils are thought to share a common bipotential progenitor, there is no evidence for a similar progenitor that gives rise only to eosinophils and mast cells. Eosinophil-committed hematopoietic progenitors (EoP) are identified within the $CD34^+$ progenitor population as IL-$5R\alpha^+CD34^+CD38^+$IL-$3R\alpha^+CD45RA^-$ cells and are distinct from the common myeloid progenitor (CMP) population that gives rise to the other myeloid lineages. Eosinophil development is controlled by the transcription factors GATA-1, GATA-2, C/EBPα, and C/EBPε. IL-3, GM-CSF, and IL-5 affect the eosinophil lineage at three different levels: (a) commitment, proliferation, and differentiation of hematopoietic progenitors in the bone marrow; (b) priming, activation, and survival in the blood and tissues; and (c) recruitment and tissue localization. Although activated T cells are likely the primary source of cytokines responsible for eosinophil differentiation and the development of reactive eosinophilia in disease, other cell types, including mast cells, macrophages, natural killer cells, endothelial cells, and stromal cells such as fibroblasts, are also producers of GM-CSF. IL-5, produced primarily by activated T_{H2}-type helper T cells and mast cells, stimulates the proliferation and differentiation of murine-activated B cells and regulates the production of eosinophils in vitro and in vivo. Both IL-3 and GM-CSF affect other hematopoietic cell lineages, whereas IL-5 is more eosinophil-specific and plays a crucial role in regulating the terminal differentiation and postmitotic activation of eosinophils. IL-5 is therefore a late-acting cytokine that demonstrates maximum activity on an eosinophil progenitor pool that is first expanded by the earlier-acting cytokines such as IL-3 or GM-CSF.[4] Although IL-3 and GM-CSF participate in the proliferation of progenitors to the eosinophil lineage, IL-5 is both necessary and sufficient for eosinophil development to proceed in vivo. In humans, IL-5 does not appear to have any effect on B cells or other lymphoid lineages, and its activity, high-affinity receptor, and functions are restricted to eosinophils and basophils. The expression of the high-affinity receptor for IL-5 is an important prerequisite and very early lineage-specific event in the hematopoietic differentiation program for both of these granulocytes. Overexpression of IL-5 is observed in many eosinophil-associated diseases and IL-5 transgenic mice develop profound eosinophilia, indicating that IL-5 plays an important role in promoting the production and function of eosinophils in vivo. These observations have been confirmed and expanded in studies of IL-5 knock-out mice, which produce basal levels of normal eosinophils in the bone marrow but do not develop blood and tissue eosinophilia, airway hyper-reactivity, or lung damage in the murine ovalbumin allergic asthma model or eosinophilic responses to helminth parasites. For these reasons, IL-5 and its receptor have proven to be excellent targets for therapeutic intervention in eosinophil-associated inflammatory diseases.

Mobilization and Migration of Eosinophils to Sites of Inflammation

In a normal individual, eosinophils produced in the bone marrow reside only briefly in the peripheral circulation in transit to

Table 70-1 Diseases, Syndromes, and Conditions Commonly Associated With Peripheral Blood Eosinophilia and/or Tissue Eosinophilia

INFECTIOUS AGENTS

Parasitic Infections

Tropical eosinophilia
Visceral larval migrans (VLM, toxocariasis)
Helminth infections
Filariasis *(Wuchereria bancrofti, Brugia malay)*
Onchocerciasis
Schistosomiasis
Fascioliasis
Paragonimiasis
Strongyloidiasis
Trichinosis
Hookworm
Ascariasis
Echinococcosis/hydatid disease

Fungal Infections

Coccidioidomycosis
Cryptococcosis (CSF eosinophilia) in HIV

ALLERGIC DISEASES

Asthma (atopic and intrinsic, nasal polyps, aspirin intolerance syndromes)
Bronchopulmonary aspergillosis
Allergic rhinitis
Urticarias (acute allergic and chronic idiopathic)
Atopic dermatitis
Acute drug (hypersensitivity) reactions (interstitial nephritis, cholestatic hepatitis, exfoliative dermatitis)

RESPIRATORY TRACT DISORDERS

Hypersensitivity pneumonitis (rare)
Allergic bronchopulmonary aspergillosis
Eosinophilic pneumonia
Transient pulmonary infiltrates (Löeffler syndrome)
Prolonged pulmonary infiltrates with eosinophilia (PIE syndrome)
Tropical pulmonary eosinophilia (TPE)
Bronchiectasis
Cystic fibrosis

ENDOCRINOLOGIC DISORDERS

Addison disease

GASTROINTESTINAL DISEASES

Inflammatory bowel disease (IBD)
Eosinophilic gastroenteritis, eosinophilic esophagitis (EE)
Allergic gastroenteritis (young children)
Celiac disease (when associated with EE)

TOXIC REACTIONS TO INGESTED AGENTS

Eosinophil myalgia syndrome (L-tryptophan)
Toxic oil syndrome

REACTIONS TO CYTOKINE THERAPIES

IL-2 and IL-2 plus lymphokine activated killer (LAK) cells
GM-CSF therapy

CUTANEOUS DISORDERS

Atopic dermatitis
Immunologic skin diseases
Scabies
Myiasis
Chlamydial pneumonia of infancy
Scarlet fever and pneumococcal pneumonia (convalescent phase)
Cat scratch disease
Eosinophilic cellulitis (Wells syndrome)
Episodic angioedema with eosinophilia
Chronic idiopathic urticaria
Bullous pemphigoid
Herpes gestationis
Angioblastic lymphoid hyperplasia (Kimura disease)

IMMUNODEFICIENCY SYNDROMES

Wiskott-Aldrich syndrome
Selective IgA deficiency with atopy
Hyper-IgE recurrent infection syndrome (Job syndrome)
Swiss-type and sex-linked combined immunodeficiency
Nezelof syndrome
Graft-versus-host-disease (GVHD)

CONNECTIVE TISSUE DISEASES

Vasculitis/Collagen Vascular Disorders

Hypersensitivity vasculitis
Allergic granulomatosis with angiitis (Churg-Strauss syndrome)
Serum sickness
Eosinophilic fasciitis
Sjögren syndrome
Rheumatoid arthritis (severe)

NEOPLASTIC, MYELOPROLIFERATIVE, AND LYMPHOPROLIFERATIVE NEOPLASMS AND SYNDROMES

Neoplastic
Ovarian carcinoma
Solid tumors (mucin-secreting, epithelial cell origin)
Chronic eosinophil leukemia
Idiopathic hypereosinophilic syndromes (HES)
Systemic mastocytosis
Myeloproliferative
Chronic myelogenous leukemia (CML) acute myelogenous leukemia (AML) and myelodysplastic syndrome (MDS)
Myelomonocytic leukemia with bone marrow eosinophilia (M4Eo, inversion 16)
Lymphoproliferative
T Cell lymphocytic leukemia
Lymphomas (T Cell, Hodgkin disease)
Angioimmunoblastic lymphadenopathy

RARE CAUSES

Chronic active hepatitis
Chronic dialysis
Acute pancreatitis
Postirradiation
Hypopituitarism

Modified and updated from Mahanty S, Nutman, TB: Eosinophilia and eosinophil-related disorders. In Middleton EJ, Reed CE, Ellis EF, et al, editors: *Allergy: Principles and practice*, ed 4, St Louis, 1993, Mosby-Year Book, pp 1077.

extravascular sites. They tend to localize preferentially in certain tissues and organs exposed to the external environment, principally in the submucosal membrane and loose connective tissue of the skin, gastrointestinal tract, genital tract, and lungs. In contrast, the acute and chronic inflammatory recruitment of eosinophils into tissues occurs primarily in response to the early- and late-phase components of immediate hypersensitivity reactions, but also in association with a variety of immunologic reactions, diseases, and idiopathic syndromes.[5] In addition, diurnal variations in the eosinophil intravascular compartment are well documented, with minimum numbers of blood eosinophils appearing early in the morning and the greatest numbers appearing late at night, mirroring circadian rhythms in circulating adrenal corticosteroids. Likewise, diurnal variations have also been documented to occur in the mobilization, recruitment, and activation of eosinophils in tissues, for example, in diseases such as nocturnal asthma.

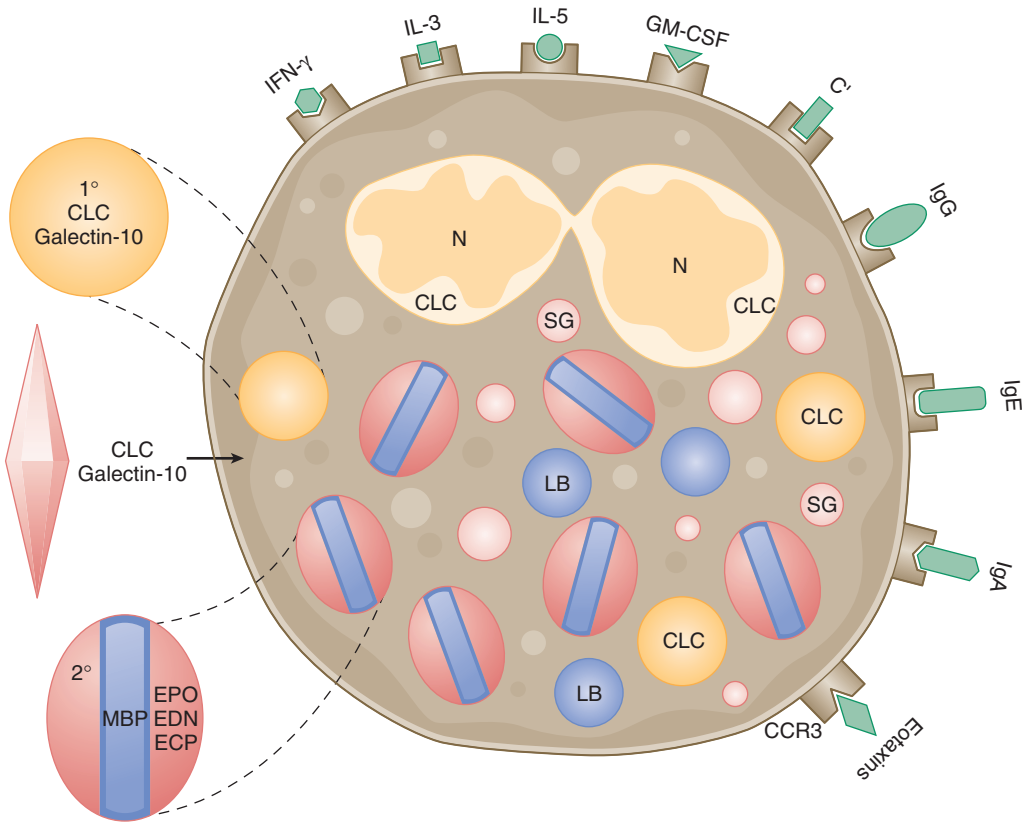

Figure 70-2 SCHEMATIC STRUCTURE OF THE MATURE HUMAN EOSINOPHIL. Primary (1°) and secondary (2°) granules, small granules (SG), and non–membrane-bound lipid bodies (LB) are shown, as are the major cell surface cytokine, chemokine, immunoglobulin, and complement receptors. Also indicated are the subcellular localizations of the eosinophil granule cationic proteins, major basic protein (MBP), eosinophil peroxidase (EPX), eosinophil cationic protein (ECP), and eosinophil-derived neurotoxin (EDN) in the secondary granule and the Charcot-Leyden crystal (CLC) protein (galectin-10) in the coreless primary granule, and the nucleus and cytosolic space beneath the plasma membrane. *(Redrawn from Gleich GJ, Adolphson CR, Leiferman KM: The biology of the eosinophilic leukocyte.* Annu Rev Med *44:85, 1993.)*

Although eosinophils may represent only a component of an inflammatory infiltrate composed of neutrophils, monocytes, and/or lymphocytes, the mechanisms by which they are selectively recruited in large numbers in certain situations remains the subject of investigation. The mobilization of eosinophils from the vasculature involves their rolling and adherence to vascular endothelium via L-selectin, followed by interactions with intercellular adhesion molecule-1 (ICAM1) through CD18/CD11a,b–dependent mechanisms and migration in response to specific cytokines or chemoattractants. Adherence via CD18-independent mechanisms involves binding to cytokine-activated endothelial cells using either E-selectin, also known as *endothelial leukocyte adhesion molecule 1 (ELAM1)* or *vascular cell adhesion molecule 1 (VCAM1)*. Selective recruitment of eosinophils likely involves adhesion to VCAM via the β_1 integrin very late activation antigen-4 (VLA-4), which is expressed by eosinophils but not by neutrophils. Because no single chemokine identified thus far is uniquely specific for eosinophils, including the eotaxins (see later), selective eosinophil recruitment likely involves the complex interaction of multiple adhesion pathways and chemotactic gradients of the eotaxins. The inflammatory mediators identified to function as potent eosinophil chemoattractants include the complement fragment C5a and platelet-activating factor (PAF), along with a number of the eosinophil-active cytokines, including IL-3, IL-5, and GM-CSF, which also prime eosinophils for enhanced migratory responses to agents such as PAF, fMLP, LTB_4, and IL-8. Other potent eosinophil chemoattractants identified thus far are approximately 1000-fold more active than PAF and C5a and include IL-2, as well as the $CD8^+$ T cell–derived lymphocyte chemoattractant factor (LCF) that utilizes CD4 expressed on the activated eosinophil as its receptor. The chemokine regulated on activation, normal T Cell expressed and secreted (RANTES), which is a chemoattractant for certain T-cell subsets and monocytes but not for neutrophils, is likewise a potent stimulus for eosinophil migration; its production by the $CD4^+$ T-cell component of cutaneous and pulmonary allergen-induced late-phase reactions may contribute to the eosinophil infiltration characteristic of these responses. The most potent and eosinophil-selective chemoattractants identified are the eotaxins (eotaxin-1, -2, -3), chemokines that bind and signal through the CCR3 receptor expressed by eosinophils. The selective signals that regulate eosinophil accumulation in tissues in eosinophil-associated diseases have been characterized. Two interrelated mechanisms for the tissue accumulation of eosinophils have been identified and shown to be linked to pathophysiology of the eosinophilic disorders. Interleukin-5 has been shown to play a critical role in the expansion and terminal differentiation of eosinophil progenitor cells in response to allergenic or other stimuli in peripheral tissues. T_{H2} T cell–derived cytokines such as IL-4 and IL-13 operate within tissues to regulate the transmigration of eosinophils from the vascular bed, a process that exclusively promotes tissue accumulation of eosinophils over other leukocytes, probably by activating eosinophil-specific adhesion pathways on endothelial cells and by regulating the production of IL-5 and eotaxin expression in the target tissue compartment. IL-5 and eotaxin likely cooperate locally to selectively and synergistically promote eosinophilia, the former working both systemically and within tissues to promote the local

eosinophil chemotactic signals provided by the latter. The regulation of IL-5 and eotaxin levels within tissues by cytokines, including IL-4 and IL-13, allows T_{H2} cells to coordinate both tissue and peripheral blood eosinophilia. These observations highlight the importance of targeting both IL-5 and eotaxin/CCR3 signaling pathways to block eosinophil-associated inflammation and tissue injury.

Mast cells, which normally reside in mucosal tissues and at interfaces with allergens, play an especially important role in eosinophilopoiesis. Mast cells provide the immediate stimuli upon activation to initiate the allergic inflammatory cascade, resulting in eosinophil recruitment during the later phases following an allergen encounter.[6] Mast cells and eosinophils are increased in numbers in nonallergic inflammatory and neoplastic conditions. Both mast cells and eosinophils express CCR3 and respond to eotaxins and RANTES (CCL5), leading to recruitment of both cell types to tissues. Mast cell–derived heparin can bind and stabilize eotaxins. Mast cells and eosinophils can interact with each other through soluble mediators or by direct cell-to-cell contact. Mast cells can also be induced to produce IL-3 and IL-5. Mast cell proteases appear to have a dual action on eosinophil functions. Mast cell–derived chymase suppresses eosinophil apoptosis and induces the release of IL-6, CXCL8, CCL2, and CXCL1 from eosinophils. Beta-tryptase, on the other hand, can cleave eotaxin and RANTES and can potentially limit eosinophil chemotaxis. Eosinophils in turn produce stem cell factor (SCF), which can attract more mast cells into the tissue and protect them from apoptosis. Simultaneous downregulation of eosinophil and mast cell activation can be achieved by inhibitory surface molecules, such as CD300a and the so-called sialic acid binding immunoglobulin-like lectins (SIGLECs), which are expressed by human eosinophils, basophils, and mast cells. Mature forms of both mast cells and eosinophils express SIGLEC8, a cell surface marker with lectin activity. SIGLEC8 induces eosinophil apoptosis and inhibits IgE-mediated mast cell activation, thereby providing a common mechanism to limit inflammation caused by the coexistence of both cell types.[7] SIGLEC8-induced eosinophil death is surprisingly augmented by the presence of GM-CSF and IL-5. SIGLECs apparently act as a failsafe mechanism that counteracts the effects of antiapoptotic cytokines that promote eosinophil survival at sites of inflammation. The SIGLECs provide a potential therapeutic target for the treatment of diseases mediated by eosinophils. For instance, Churg-Strauss syndrome and chronic urticaria, both characterized by increased tissue eosinophilia, have been successfully treated with intravenous immunoglobulins that contain SIGLEC8 autoantibodies. These autoantibodies are agonistic and promote eosinophil cell death.

Eosinophil Activation in Disease: Eosinophil Heterogeneity

Eosinophils secrete their preformed granule constituents and newly synthesized lipid, cytokine, and peptide mediators of inflammation upon stimulation (Fig. 70-3). Peripheral blood eosinophils from patients with eosinophilia and eosinophils from an inflammatory environment within tissues are heterogeneous with regard to their capacity for stimulation and secretion of the described mediators. Eosinophils from blood and tissues of patients with eosinophilia differ from their normal counterparts by a variety of morphologic, biochemical, and functional characteristics, some of which appear to be linked to a significant decrease in cell density. A distinction is made between the populations of "normodense" (normal-density) and "hypodense" (light-density) eosinophils isolated from the peripheral blood and tissues. The blood of normal individuals contains less than 10% of eosinophils with densities less than 1.082 g/mL, whereas patients with eosinophilia can have markedly increased numbers of hypodense cells. Hypodense eosinophils possess a variety of properties consistent with their being primed and/or activated in vivo. Activated hypodense eosinophils are morphologically characterized by increased vacuolization, decreased granule size and content of granule cationic proteins such as MBP, and increased numbers of cytoplasmic lipid bodies. The numbers of surface receptors for a variety of eosinophil-active agonists, including complement cleavage fragments of C3 (CR1 and CR3), immunoglobulins (IgE, IgA), cytokines, and PAF, are expressed to a greater degree by hypodense eosinophils, as are a number of membrane surface antigens such as CD4. Functionally, hypodense eosinophils show increased metabolic activity, oxygen consumption, and generation of superoxide anion, as well as an increased capacity for the synthesis and secretion of LTC_4 and certain cytokines, enhanced chemotaxis, and augmented cytotoxicity for antibody-coated targets.

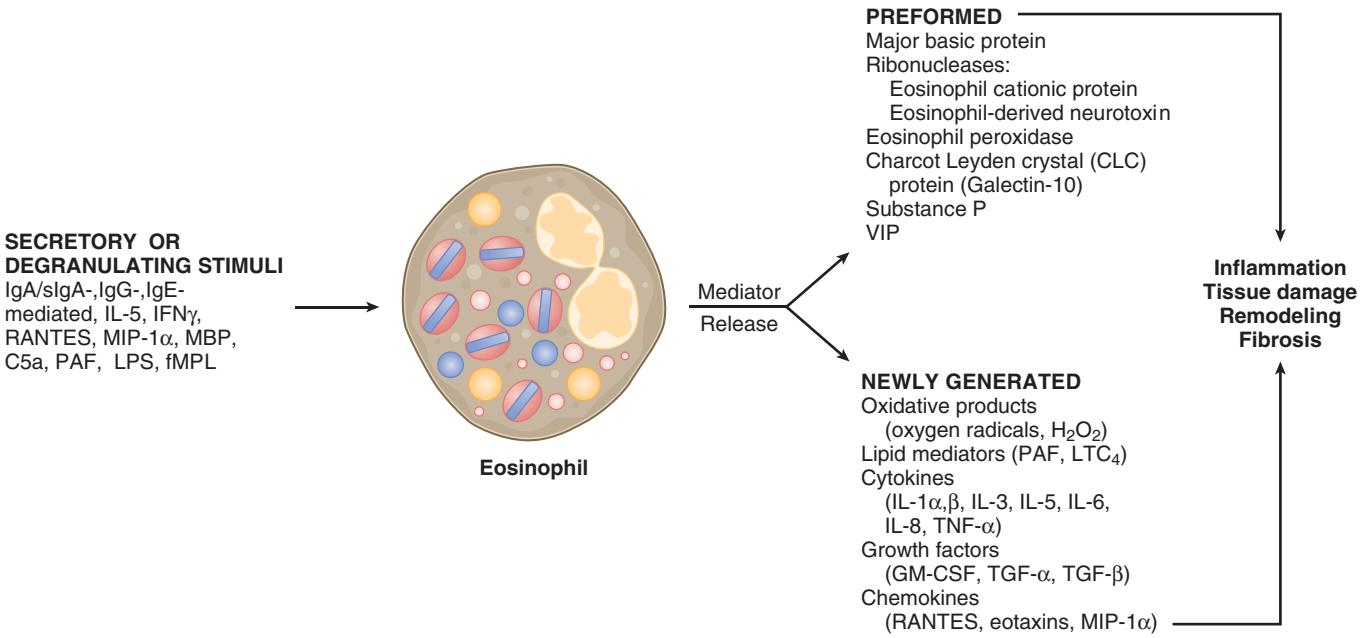

Figure 70-3 EOSINOPHIL SECRETORY/DEGRANULATING STIMULI AND EOSINOPHIL-DERIVED INFLAMMATORY MEDIATORS. The listed factors have been shown to stimulate the secretion of inflammatory mediators from the eosinophil. These mediators may be either preformed, such as the eosinophil granule-derived cationic proteins, or newly generated mediators such as oxidative products, lipid mediators (e.g., LTC_4), inflammatory or hematopoietic cytokines, chemokines, and growth factors. Release of these mediators leads to tissue inflammation, damage, remodeling, and fibrosis. *(Redrawn from Furuta GT, Ackerman SJ, Wershil BK: The role of the eosinophil in gastrointestinal diseases.* Curr Opin Gastroenterol *11:541, 1995.)*

The mechanism by which eosinophils are activated in vivo has been largely defined through the in vitro analysis of factors capable of prolonging eosinophil survival and inducing the development of the hypodense phenotype. The incubation of normal peripheral blood eosinophils with GM-CSF, IL-3, IL-5, and interferons (IFN-α and IFN-γ), either alone or in co-culture with endothelial cells or fibroblasts, induces the development of the hypodense activated phenotype characteristic of eosinophils isolated from patients with hypereosinophilic disorders. In addition, the eosinophilopoietic cytokines (IL-3, IL-5, and GM-CSF) prolong the survival of mature normodense and hypodense eosinophils in vitro (and possibly in vivo in tissues, likely by preventing apoptosis). The exposure of eosinophils to the previously discussed factors in vitro does not precisely recapitulate all the functional characteristics of the in vivo activated, tissue-derived cell, suggesting a requirement for additional, as yet undefined, factors that may include interaction of adhesion receptors with their ligands during eosinophil recruitment and migration into the tissue or stromal cell–derived factors.

Precise relationships between the percentage of hypodense eosinophils and the clinical nature of an eosinophilic disorder have not been clearly defined. Rough correlations have been reported between disease severity and numbers of circulating hypodense eosinophils for particular hypersensitivity disorders such as allergic asthma and allergic rhinitis. However, a significant overlap exists in the percentage of hypodense peripheral blood eosinophils in hypereosinophilic disorders of varying severity, such as bronchial asthma, HES, and certain helminth infections. Because eosinophils reside primarily within tissues for the majority of their lifespan, it is not surprising that their heterogeneity in the peripheral circulation is at best a crude reflection of disease severity. In vitro models of eosinophil heterogeneity suggest a number of pathways for the development of eosinophil subpopulations, including acute exposure to mediators generated in immediate-type hypersensitivity reactions (e.g., PAF, eosinophil-active cytokines such as GM-CSF, IL-3, IL-5, IFN, or TNF) or more chronic exposure to eosinophil-active cytokines in combination with as-yet-undefined factors in tissues as discussed earlier. Regardless of the specific mechanisms or mediators underlying eosinophil priming or activation, the development of eosinophil heterogeneity as a reflection of the functional, proinflammatory capacity of the cell in vivo indicates that these processes can be manipulated therapeutically. For example, in disorders such as HES, in which excessive levels of IL-5 have been demonstrated therapies aimed at modulating IL-5 levels to normalize the eosinophil phenotype and attenuate the eosinophilia have been developed. Such examples include the use of cyclosporin A or IL-5 neutralizing antibodies to produce clinical remissions in patients with steroid-resistant HES. Cyclosporin A has been shown in vitro to inhibit IL-5 production from T-cell clones derived from patients. By contrast, because eosinophil infiltration of certain types of malignancies, including colon and lung cancers, may be associated with an improved prognosis, it may be advantageous to induce tissue eosinophilia and enhance their cytotoxicity. Studies suggest novel roles for the eosinophil in tumor immune surveillance and antitumor effector cell responses in animal models.

EOSINOPHILIA AND EOSINOPHIL-ASSOCIATED DISEASES, SYNDROMES, AND INFLAMMATORY REACTIONS

Assessment of Eosinophilia

Histochemical staining with eosin-based stains is the standard means of identifying eosinophils in both blood and tissues (hematoxylin and eosin) (see Fig. 70-1). Other histochemical dyes such as chromotrope 2R are more definitive in tissues, and Fast Green or Luxol Fast Blue can be used in blood smears or cytocentrifuge preparations to specifically distinguish the mature eosinophil from polymorphonuclear leukocytes and basophils. The chemical characteristics of the fluid or tissue in which the eosinophil is analyzed, and most important, the eosinophil's degree of maturity, activation, secretion, and/or degranulation can induce significant variability in histochemical characteristics using Romanovsky-type metachromatic stains. For example, eosinophils in urine, as found in eosinophilic cystitis or interstitial nephritis, are best detected with a Hansel stain. As a result, it is now appreciated that the definitive identification of the eosinophil's participation in a particular inflammatory response or disease may require immunochemical localization using specific monoclonal or polyclonal antibodies to eosinophil-specific granule proteins such as MBP, eosinophil peroxidase, or ECP, all of which have been used to identify eosinophil infiltration and secretion or degranulation in tissues where they have been missed by more classic histochemical techniques. For peripheral blood, manually performing absolute eosinophil counts or using automated counting systems will provide a much more reliable estimation of eosinophil numbers than will microscopic differential counting of blood smears combined with total leukocyte counts, especially in situations in which there is an absolute leukocytosis or leukopenia for another lymphoid or myeloid lineage. Circulating eosinophils are generally present in low numbers in normal healthy individuals with consensus absolute counts ranging from 35 to 350 eosinophils/mm^3 (mean 125 for adults; 225 for children under 12 years). The broad range of variability in normal blood eosinophil levels reflects the multiple sources of both subtle and more obvious physiologic effects due to diurnal variation in endogenous glucocorticoid levels, degree of atopy in the general population, and other factors that can include exercise, emotional stress, and hormonal influences of the menstrual cycle.

Clinical Assessment of Eosinophilia: Peripheral Blood Versus Tissue Eosinophils

The low numbers of eosinophils in the blood compared with neutrophils and lymphocytes, coupled with their primary localization in tissues, makes accurate quantitation and interpretation of blood eosinophil counts difficult. As noted earlier, a cell differential count fraught with sampling error when eosinophils constitute less than 3% to 5% of total peripheral blood leukocytes. Furthermore, automated cell counters may not accurately enumerate eosinophils unless they are present in sufficiently high numbers, and they can miss eosinophil peroxidase-deficient cells. A manual differential or absolute cell count should be performed if low-to-moderate eosinophilia is suspected in the clinical evaluation of a patient. The number of circulating eosinophils in the blood reflects a complex interplay of factors, including rates of development and transit from the bone marrow, margination, and subsequent emigration into tissues through postcapillary venules. Because the eosinophil is primarily a tissue-dwelling cell and is present in extravascular sites at levels several hundred-fold more than in peripheral blood, and because blood levels may vary significantly as noted earlier, circulating cells reflect only those in transit between the marrow and their final functional destination. Normal adult bone marrow contains approximately 3% to 5% eosinophils, with approximately 40% mature cells, and migration of eosinophils from the marrow into the blood takes approximately 3.5 days. The half-life of the eosinophil in the peripheral blood of normal individuals is approximately 18 hours, with an average blood transit time of approximately 26 hours, similar to that of neutrophils. Daily mean turnover is approximately 0.2×10^9/kg, and the bone marrow has a postmitotic reserve of approximately 0.1×10^9 eosinophils/kg. Under ideal steady-state conditions, one would anticipate peripheral blood eosinophil levels to be proportional to levels in normal tissue compartments. In contrast, during certain acute inflammatory or immune responses, temporal lags have been observed to occur between infiltration into reactive tissue sites and the induction of eosinophil development and emigration from the marrow, resulting in the development of eosinopenia or delayed blood eosinophilia, or both. Moreover, in more chronic eosinophil-associated inflammatory conditions, tissue eosinophilia may be prominent in the absence of any peripheral blood

eosinophilia, for example, in certain skin diseases. Thus the clinical assessment of peripheral blood eosinophilia, although diagnostically important, must be interpreted with these caveats in mind.
